And maybe you should try out rec.radio.amateur.know_it_all. I'm sure
you'd be in good company.

John

I use EZNEC 5 nearly every day. It saves me time & money. I can minimize my physical work as well. At 71 years old that is getting more important every day. Last week I took down my Fan of dipoles and put up a 40m half wave in series with an 80 meter half wave, fed at 33% from one end. The wire was handy and so was the room. What a waste and in 90 degree + weather too. If I had modelled it first, I would have done it. Hard to feed everywhere and the low activity seem to endorse the computed patterns.

I ran an inverted Vee through EZ5 with 43 foot wires on each side and it looked as good as anything on 40 & 80M and was easy to tune about anywhere. The testing has supported that the 30M and up patterns are not nearly as useful as the corresponding dipoles, but it does work everywhere. I got the 43 foot wires by simply folding the excess from an 80M dipole and taping them. Nothing permanent, no $ spent. I will likely keep this for 40 & 80. Probably back to adding in a couple of dipoles for 30 & 17 in a fan configuration while I consider my first venture into my first Quad effort.

20-15-10 are covered with an A3S Cushcraft at 60 feet. I don't understand it, but it works good.

I have seen two commercial antennas advertised that are each 43 feet tall, and have no traps/stubs, etc.
There appears to be a 4:1 balun at the feedpoint. Mentioned, is the requirement to have a tuner at the driving end of the feedline, and max

VSWRs in the 4:1 range.

Playing around a bit with EZNEC, the feedpoint impedances over the
operating range have some large swings. Can anyone shed light on how
effective the antenna should be?

That is a disease that affects, as a SWAG, about 80% of the core population here.

Then there are the people that ask questions because they are trying to actually build something. Who almost always get what is effectively GobbldeeGook in response.

All they just want to know how to make something that is "OK, works good enough" and they have to wade through dozens of useless responses to _maybe_ get one that's worthwhile.

Welcome to rraa, where no one "important" ever agrees.

Hi Walt,

The focus seems to have shifted away from the matching hardware previously described to:
>What I'm really concerned about is the reflection coefficient at the
>output of the tank circuit of the RF power amp.

It includes a point argued by many, and which you make a condition of success for your argument:
>Being non-dissipative
>it cannot absorb the reflected power, so it must re-reflect it.

Your argument now applied at two points, one not illustrated in your references (the source):
>Therefore, my position is that its reflection coefficient rho = 1.0,

The counter argument:
>My critics say that a rho = 1.0 cannot be established when the virtual
>short is caused by wave interference.
which they express NOT as a condition of the tank circuit, but of the matching hardware.

>However, if Best's Eq 8 is
>valid,

You have acknowledge that experts in math whom you trust say it is valid. This yields a paradox. By all the shifts in focus, it is apparent that:
1. You are both right;
2. You are both wrong.
3. One of you is right, and one of you is wrong;
more likely given the drift of focus:
4. You are at cross purposes and arguing two different things.

>Now that I've narrowed the problem down, what do you believe is the
>answer?

You have not narrowed the problem down at all. It is composed of a succession of premises that all have arguments for-and-against them.

This compounds the uncertainty. It also brings the hazard of any
single premise being rejected bringing down the entire goal you are
pursuing.

* * * * * * * * * * * * * * * * * * *

To put this bluntly, let's test the assertion repeated here:
>output of the tank circuit of the RF power amp.
>Being non-dissipative
>it cannot absorb the reflected power, so it must re-reflect it.

Odds are, you will lose support from at least half of the readership
for this statement alone - and it isn't even in your written work that
I've provided links for, and it certainly doesn't appear in Johnson.
It is not discussed by the experts in math either. It is a flyer, a
leap of faith whose validity is now emeshed with the outcome of
another problematic discussion.

Steve's opinion:
>viz.
>   "A total re-reflection of power at the match
>   point is not necessary for the impedance
>   match to occur."
offers NOTHING to the matter of non-dissipation.

Odds are, Steve could easily lose support from at least half of the
readership for this statement alone. Unfortunately, that doesn't
leverage your position one iota.

There are too many irons in the fire.

Thank you for your insightful response, Richard. However, I must plod
on, and introduce the results of my own measurements, the data of
which appear in Chapter 19, Sec 19.14 of Reflections 3. Using a
Kenwood TS-830S I measured the parameters required to prove the output
source resistance of the tank circuit of its RF power amp is non-

dissipative. The measurements also prove that the reflected power
incident on its output is totally re-reflected. From reading an
earlier post of yours, Richard, I know you have read this portion of
Chapter 19, and you agreed with it. My measured data conflicts with
Best's Eq 8, so there's got to be a valid answer to this dilemma, but
where?

Walt

Hi Walt,

Yes, I am very familiar with your bench work. I am very annoyed by those who trivialize it. I am further annoyed by those who patronize you to then shift the parameters to explain something else - completely abandoning you.

However, I also acknowledge that I can hurt your feelings about where I stand on these matters. Yes, to a limited degree, I do agree with much of your assessment, but I do not follow it into the arena of where you express it as being "non-dissipative."

However, my denying this proposition does NOT mean I dispute your other proposition of complete reflection. This cross connection of several topics is where things get overly complex and gives the entire discussion the appearance of a house of cards.

I cannot tell what your agenda is, but the material you quote as source, and for which I have provided links to in this thread - all seem a subtext to non-dissipative sources. Attention directed towards this pursuit of matching points rendered in stubs seems like tea leaf reading to resolve a larger issue.

As a student, tech, and engineer employing a LOT of precision waveguide technology, I am quite comfortable with the components and topologies you describe. Arguments for wave interferences being rendered into useful circuit constructs (that is, constructed on the basis of wave interference) has been with us easily since the early 40s. One component, the ATR tube, is one I have handled and replaced to insure the proper operation of RF paths being steered in waveguides. One proviso, however => for any of these "virtualizations" to work, they require a physical (and dissipative) element as the initiator. Waves do not interfere without the presence of a physical element (often some form of detector, or minimally a load).

Thanks again Richard, for your insightful response. And goodness no, Richard, you won't hurt my feelings. I like being correct, but if I'm not I surely want to be told about it. This situation is no different.

However, if you're not following me on the 'non-dissipative' path, I'd like you to review the last portion of the TS-830S experiment, and follow the numbers. If you don't have that material in front of you, you can find it again on my web page at www.w2du.com. Click on 'Preview Chapters from Reflections 3', and then click on Chapter 19A, which is a part of Chapter 19 in the 3rd edition.

Observe that when the load impedance is changed from 50+j0 to the complex impedance 17.98 + j8.77 ohms, the plate current rose expectedly from 260ma to 290ma. This change occurred because the amp is now mismatched, and the pi-network is also detuned from resonance. The unwashed would conclude that the reflected power caused the increase in plate current. However, one will also observe that after the pi-network has been retuned and adjusted to again deliver all the available power into the otherwise 'mismatched' load (which is now matched to the source), the plate current went back to it's original value, 260ma. In addition, the amp returned to deliver 100w into the complex impedance at the line input, with the 30.6w of reflected power in the line, and adding to the 100w of source power, making 130.6w incident on the mismatched load, absorbing 100w and reflecting 30.6w.

IMHO, these data prove beyond doubt that the pi-network not only didn't absorb any of the reflected power, but totally re-reflected it.

In my book this says the pi-network reflection coefficient rho =3D 1.0.
How can anyone disagree with this?

Walt

Hi Walt,

There is absolutely NOTHING that I can dispute in your numbers or method. However, as to "dissipation" this says nothing.

As for what it says about the reflection coefficient, I would agree with you. However, the math and the math experts you speak of - they are not answering the model we are examining above. You distracted them with stubs and reflecting waves.

If you cast this agreement in the reflection coefficient back into effects purported to exist in the matching with stubs model, we may yet argue.

> IMHO, these data prove beyond doubt that the pi-network not only didn't absorb any of the reflected power, but totally re-reflected it. In my book this says the pi-network reflection coefficient rho = 1.0. How can anyone disagree with this?

*** Nothing further useful about the topic is to be found below ***

There is a curious side bar to this found at:
http://www.w5big.com/purchase4170c.htm
Observe the second data screen that purports to examine a mismatch through a length of both RG58 and RG59 terminated with 100 Ohms.

Of particular note is the distinct transition from the Zc of 50 Ohms to the Zc of 75 Ohms and the similarly distinct transition from the Zc of 75 Ohms to the termination R of 100 Ohms. Note that the transitions both span a distance of 2 feet. 2 feet is not insubstantial compared to connection technology that spans, probably, no more than one tenth that distance. Whence the extra 11 inches on both sides of the connection plane of either connection?

In the physics I've been studying for the past 10 years, near fields, this would not be unusual. In fact it would be expected. There is a transition zone (in waveguide design, there would be a taper or a sweep section to anticipate this and they would be physically large in terms of wavelength) not a transition cliff.

Similarly, at the connector to your TS-830S, there is a zone that surrounds it that only approximates the 50 Ohm which occurs (in the terms of this link's demonstration) some distance away, deep inside your TS-830S.

To me, dissipation inhabits this zone (certainly large enough for the tube and tank to occupy) and embraces the match with a complex addition of phases that could result in loss or even gain. This is also to say that I do not subscribe to dissipation being all about loss - especially when the hand of man is on the tuning knob instead of letting the chips fall where they may.

Walt,  I can only get your 1.0 - j1.1547 normalized impedance value
(looking into the line towards the normalized load of 3.0) if I move 60
degrees, not 30, from the load towards the generator.  I'm also assuming
a lossless line.  Sincerely, and 73s from N4GGO,

Hello JB, thank you for the response. I'm sure I understand what's
going on. When you view the Smith Chart at the unity resistance circle
with a 3:1 mismatch the normalized impedance there is 1.0 - j1.1547,
as you stated. However, a radius through that point yields a voltage
reflection coefficient rho =3D 0.5 @ -60=B0. In other words, the radial
line intersects the periphery of the Smith Chart at -60=B0.

As I'm sure you know, reflection degrees equals two electrical
degrees. Therefore, the normalized impedance 1.0 -j1.1547 ohms occurs
at 30=B0 rearward of the load. That  OK?

In the absence of a Smith Chart here's an easy way to determine the
reactance appearing at the unity resistance circle for any given
degree of mismatch:

                                                         1/(sqrt SWR/
SWR-1)

Well, I'm not clear what you mean by "rearward of the load". At 60 degrees toward the generator the normalized impedance looking into the line is 1.0 - j1.1547 ohms and that corresponds to a reflection coefficient of -j1.1547/(2-j1.1547) or alternatively, 0.5 @ -60 degrees (sorry my char set doesn't do Steinmetz notation). So I think we're in agreement here. What more needs to be said? Now put in a shorted stub (of appropriate length at the desired frequency) in series to tune out (cancel) the reactive part of the line impedance. The combination of the series stub and the line will appear as 1.0 + j0 to the generator/source and the reflection coefficient is now 0. How could it be anything else (at the desired frequency) in this scenario? You don't need a discussion of travelling waves to arrive at the correct answer. The reflection coefficient corresponding to a normalized (say to 50 ohms) impedance zx = Zx/50 is rho = (zx - 1)/(zx +1). Clearly a values of rho = 1 + j0 or -1 + j0 correspond to a zx values of infinity (open circuit) or zero (short circuit), respectively.

You might want to think of the shorted line stub as inside one box and the transmission line + 150 ohm load in another black box. Let's assume someone hands you these two boxes and you have no idea what's inside but you do have access to set of terminals (input port) on each box from which you can measure steady-state impedance of each. At some frequency you find the normalized input impedance on one box is +j1.1547 ohms and on the other box at that same frequency it is 1.0 - j1.1547 ohms. Now you connect the boxes is series and measure the impedance of the series combination again at that frequency. The point I'm making here is that at the terminals of either of the boxes you measured the impedance at some frequency - it doesn't matter what's inside the box. (Of course the impedance behavior over a range of frequencies certainly is dependent on the circuit topology within the box.) Sincerely,

com

Thanks again for the response, JB. What I mean by rearward of the load
is simply going toward the source from the load. But are we in
agreement? We probably are as long as we agree on terminology
regarding the Smith Chart. The unity resistance circle for a 3:1
mismatch yields a normalized impedance of 1 - j1.1547 as you know. As
I said in my previous post, a radial line passing through this point
on the unity-resistance circle joins the periphery of the Chart at
-60=B0. It important to note that this -60=B0 is reflection degrees, which
is two-times greater than degrees along the transmission line.
Therefore, the normalized line impedance of 1 -j1.1547 appears at 30=B0
from the load toward the source on the xmsn line, not at -60=B0. Hope
we're in agreement on this.

Walt

I found an adapter in my junk box that goes from a BNC to something similar to a male N type. It will not mate up to a female N connector.

A normal N male connector has the center that is just about even with the shell that screws onto the female end. This connector has the male part sticking out about 1/4 of an inch past the shell. It will fit the female N connector except when I go to screw them together, there is not enough threads to mate and make a good mechanical connection.

Anyone know what type of connector this is ?

Two suggestions come to mind.  First, have you tried Pasternack's
connector identifier PDF (www.pasternack.com/pdf/catalog/
ConnectorIdentifier.pdf) or equivalent?  Second, could it be a damaged
BNC-to-N?  It seems strange to have the pin sticking out that far; it
would be inviting damage to the pin.

Cheers,
Tom

I have not seen that url. I did not see one like it there.

It could be dammaged. It is not just the center pin that is sticking out
past the threaded shell, but the whole inside part of what would be a normal

N connector. It will pass power, just the threads will not screw together.

Hiya...
Newly minted =93non technical=94 ham here :-)

Been a SW DX=92er for many years and decided to get my ham ticket recently.

Now that I've decided on what to get for my first ham radio, (TS-590s) I'm moving on to deciding on an antenna. The goal will be DX'ing the ham bands with phone and eventually CW. I'm looking for an antenna set up that will work on 10 to 80 meters. Of course, multiple specific antennas would be an ideal, but that is not in the cards. I've had a few options in mind. All of course, would be coupled with an antenna tuner if the internal auto tuner on the radio cold not do the job.

1. Set up a butternut HF9V on a roof mount approx 30-35 feet above the ground with tuned radials. The problem being, the footprint of my

roof is only 35' x 35'. With the antenna set up in the center of the roof, there will be only a max of 17" to string the radials outward. I'd have to "snake" them in order to fit and figure out how to secure them. Another draw back is that verticals tend to be noisy. Not to mention shelling out money for a roof mount set up and putting lag bolts in up there.

2. Set up a GAP Titan on a roof mount approx 30-35 feet up. No radials needed with that antenna, but I have been told/read that unless perfectly assembled, they don=92t work as advertised. Again... Verticals can be a noisy and the set up time and cost.

3. Set up a Chameleon V11 or v12 vertical rigid diepole on a non conductive mast mounted to brackets on the side of the house with the feed point of the antenna being about 25 to 30 feet high. This antenna is advertised as a "dipole" and does not need any radial set up. There have only been a few reviews of this antenna. All are very favorable, but is it too good to be true??? A vertical mounted rigid antenna working with no radials even if it is being called a dipole ??? With this antenna, I=92d be able to avoid having to use a roof mount. Just mast it to the side of the house high enough for the bottom pole to clear the roof. A simple install. Still=85 No idea at all how good this antenna is.

4. Go with a wire antenna. I had in mind using the Buckmaster off center fed diepole. The eight band 300 watt version has two pole lengths of 90' and 180' respectively. I had in mind hooking the center feed point to the apex height of the side of my house to a non conductive hook I can screw in up there. There is enough length of space on my lot to let both the long and short pole ends to extend out and down in and inverted V. I'd secure the pole ends to the ground with plastic cord and non conductive ground spikes so that the receiving wire was still elevated 8 to 10" above the ground. The feed line would not go straight down from the apex. Since the top of the roof is right where the feed point would be secured, I'd pull the feed up and right on to the roof. From there, run it across the roof and down the other side of the house a few feet and right into the shack on the top floor on the other side of the house. The upside... No ground or radials needed, no expensive or troublesome set up, if need be I can take the thing down in fifteen minutes with no problems at all with just a small hook left on the side of the house. It would also be a more "quite" antenna vs. a vertical like the ones mentioned above. The down side... It would radiate well east and west, but not well off the poles north and south. Also... The very top of the antenna would not be elevated above the house, so about ten feet of each pole up top would be obscured on one side by the house.

I also thought about using my current short-wave listening antenna to transmit with, but I think I=92d have to change the matching transformer. I=92ve got an Inverted L with a 30=94 vertical length and 40=94 horizontal length. That receiving wire is stranded copper made specifically to be used as receiving wire. It is attached to a matching transformer (an ICE-180) that is mounted to the foundation of

my house about two feet off the ground. That ICE-180 is in turn
directly grounded to an 8 foot brass grounding rod. The feed line is
50 ohm coax that runs up the side of the house from the ICE-180 and
into the shack. The ICE-180 is a =93receive only=94 item and I don=92t thin=
k
you can load it up.

Well... That's about it...

Any comments, advice or suggestions would be appreciated.

Thanx in advance.

Michael

That link didn't work, but is this the one you meant to publish?

http://www.pasternack.com/pdf/catalog/ConnectorIdentifier.pdf

73
John VK2KC

> Anyone know what type of connector this is ?

Two suggestions come to mind. First, have you tried Pasternack's
connector identifier PDF (www.pasternack.com/pdf/catalog/
ConnectorIdentifier.pdf) or equivalent? Second, could it be a damaged
BNC-to-N? It seems strange to have the pin sticking out that far; it
would be inviting damage to the pin.

Cheers,
Tom

It could work pretty well as far as verticals go,
but all the tuned radials will be a pain to deal with
for all bands. It would be easier to ground mount, but=20
of course, being the antenna is lower, the local space
wave on the higher bands will not be as strong as elevated.
But it will make little difference on the lower bands
as long as you plant the ground radials. One plus to the=20
ground mount, is the radials don't need to be tuned.
They can be any length and still help. Where as elevated,
untuned radials that are not in use are fairly useless.

>=20

Never tried one. But it wouldn't be in my cards if I=20
were in your position. Also, verticals are no noisier
than any other antenna. It just depends on the polarization
of the noise signal. Noise is RF just like any other signal,
and follows the same rules.

New one on me.. Never have seen one.. Sounds like a=20
typical half wave design..

>=20
> 4. Go with a wire antenna. I had in mind using the Buckmaster off
> center fed diepole. =20

I'm not a fan of off center fed dipoles.=20
But overall, I think a wire antenna is your best
choice if you want a decent NVIS signal on the=20
lower bands.=20
But... I would use a center fed dipole.=20
If you require all bands, I would use the=20
largest dipole you can squeeze in, preferably=20
80m size, "60-65 feet per leg", and feed it=20

with ladder line, and using a tuner at the rig.

Myself, I prefer parallel coax fed dipoles, but=20
I usually don't run every single band.=20
IE: I have 80 and 40 dipoles on the same coax
feed. I'm on one of those bands 90 percent of the=20
time. I can slap a tuner inline if I want to=20
work one of the other bands. Some loss, with it=20
still usually works well enough to talk.
>=20

ink
> you can load it up.

An inverted L can work fairly well in some cases,
but you would need to rework the feed system to=20
transmit. And a ladder line fed dipole would probably
outplay it anyway for most all bands.
=20
>=20

Anyway, my vote is ladder line fed dipole for all
bands 80-10. Will need a tuner though.. Or use Cecils's=20
tunerless method with cut feed line lengths.

'Captain' Kirk DeHaan said the following on 5/22/2011 11:04 AM:

> I'm living in a wooded area and am trying to hit our club repeater reliably. It's cloudy now so I'm and getting a bit of ducting but I have a lot of trees, mostly poplars, in the direct path. I would have a line of sight if not for the trees as I'm up enough in altitude. I can cut the trees, they're mine, but finding the right ones is difficult and i don't want to waste the whole grove.
>
> I go from keying the repeater with no intelligible signal to not being able to hit it. Today I actually have an S meter reading due to the clouds. I am currently using a J-pole and will put up a Yagi soon but wonder if NVIS would work on 2m? I have only seen references to it being applied in HF.
>
> 'Captain' Kirk DeHaan
> N6SXR

I purchased a 10 element 2m Yagi and installed it today. I can now hit the repeater in question full quieting. The other benefit is I can hit the one other repeater that I could not even hear before. I am quite happy now. :-) Now I don't have to cut down any more trees, other than those I am selling.

Thanks for all the input from everyone. Problem is solved!

This is vintage "Reflections" stuff Walt, where you try to explain what is =
happening with one foot in the time domain and the other in the frequency d=
omain.

> To begin, the stub generates a new, secondary,
> canceling reflection that cancels the primary reflected wave generated
> by the mismatched line termination.

I can see you heading to re-re-reflections etc.

Thing is that in the steady state (and your Smith chart works ONLY in the s=
teady state), the reflection on the first mentioned (lossless) line (with t=
he 150 ohm load) is determined entirely by its characteristic impedance and=
 the load impedance. The ratio of V/I looking into that line section is giv=
en by those parameters and line electrical length.

Sounds boring, but the reflection on the second mentioned (lossless) line (=
with s/c termination) is determined entirely by its characteristic impedanc=
e and the load impedance. The ratio of V/I looking into that line section i=
s given by those parameters and line electrical length.

The ratio of V/I at the node where both lines are joined is given for a shu=
nt stub by the inverse of the sum of the inverses of V/I for each.

You can think about reflections from on line entering the other, and energy=
 sloshing around, but the Smith chart is not going to help you because is i=
s simply a graphic computer for finding Gamma, calculating Gamma along the =
line, adding B, G etc by following lines of constant G, B etc.

If we tried to explain the common microwave three screw tuner using re-refl=
ections, virtual open circuits to rearward traveling waves, conjugate mirro=
rs etc, total re-reflection etc, we would complicate something that is easi=
ly explained using a Smith chart (and the underlying maths - The Telegraphe=
r's Equation) and quite conventional AC circuit theory.

In fact, a three stub tuner with practical (ie lossy) lines can be explaine=
d fairly easily using a Smith chart, even if a little fiddly iteration is n=
eeded to deal with lossy elements.

If the total re-reflection etc concepts are hard to translate from mental m=
odels to mathematical expressions for simple scenarios, they become near im=
possible for more complicated topologies and 'real' components.

Owen

Thanx for the response... I myself and leaning the way of the wire die
pole.  It appears to be not only the most economical solution, it will
probably give the best results. i also did consider a ground mounted
43 foot DXE Thundebolt MBVA 1UP

> My critics say that a rho = 1.0 cannot be established when the virtual
> short is caused by wave interference.

A reflection is what happens to a single wave at an impedance discontinuity. The redistribution of energy associated with interference is technically not a reflection since it involves the superposition of two (or more) waves. As a result, reflection mechanics cannot be used to explain interference effects. The "virtual short" is the *result* of the combination of physical reflections plus conditions associated with interference, i.e. the "virtual short" is not the *cause* of anything - it is the *result* of reflections plus interference.

Most people deal only with reflected voltages where the interference is transparent. When we start dealing with reflected power, interference is NOT transparent as it must be recognized to be able to track the energy through the system.

If we superpose two identical waves of 100 volt at zero degrees, we obviously get 200 volts at zero degrees. However, when we recognize that in a 50 ohm environment some distance away from any source, we have taken two 200 watt waves and created a single 800 watt wave, the question arises: Where did the extra 400 watts come from? The answer is from constructive interference which requires 400 watts of destructive interference in the opposite direction in order to satisfy the conservation of energy principle. When interference is involved the virtual power reflection coefficient may not be the square of the

physical voltage reflection coefficient.

news:faeac170-e7f6-4714-9512-6236b72d86b7@c26g2000vbq.googlegroups.com...

Hiya...

Newly minted �non technical� ham here :-)

Been a SW DX�er for many years and decided to get my ham ticket recently.

Now that I've decided on what to get for my first ham radio, (TS-590s) I'm moving on to deciding on an antenna. The goal will be DX'ing the ham bands with phone and eventually CW. I'm looking for an antenna set up that will work on 10 to 80 meters. Of course, multiple specific antennas would be an ideal, but that is not in the cards. I've had a few options in mind. All of course, would be coupled with an antenna tuner if the internal auto tuner on the radio cold not do the job.

Any comments, advice or suggestions would be appreciated.

Thanx in advance.

Michael

Dear Michael: Let us know your call-sign when it arrives.
I too recommend a wire dipole with equal lengths of wire each side of a ladder-line feed. Avoid the use of so called 4:1 whatever. Consider finding a 275 Watt Matchbox (a larger item also exists). It is ideal for efficiently coupling energy from a coax transmitter to ladder-line fed dipole.

Work on mastering CW as that may be the most effective way to make DX contacts with low power and a low antenna.

Enjoy. 73, Mac N8TT

The first antenna you buy or build will be a disappointment.

Bigger is always better than smaller with an antenna. We all
eventually learn that.

A multi band antenna is like a Swiss Army Knife. (I use both!) They
are very handy, but it is always easy to find a better solution to the
task at hand.

Cautiously imitate the success of others before you get too serious
about innovating. There are reasons why some antennas or equipment are
or are not popular.

Locally here in Central North Carolina the recommendation to new Hams
is what is known as the G5RV antenna. There are a lot of respected
vendors who offer G5RV's at competitive prices. You will need some
kind of tuner sooner or later.

Get on the air! Find out what direction you really want to go.

Let me try an example in ASCII to see if it can work.

--50 ohm--+--1/2WL 291.3 ohms--50 ohms

Given: The steady-state forward power, Pfwd1, on the 50 ohm line is 200 watts. The steady-state reflected power, Pref1, on the 50 ohm line is zero watts. 200 watts of steady-state power is delivered to the 50 ohm load. The power reflection coefficient, rho^2, is 0.5 at point 'x' and at the load. The power transmission coefficient, 1-rho^2, is 0.5 at point 'x' and at the load.

The steady-state incident forward power, Pfwd2, at the 50 ohm load is 200/0.5=3D400 watts. The steady state reflected power, Pref2, at the load is 400(0.5)=3D200 watts.

There are four superposition components:

1. The component power reflected from point 'x' back toward the source is Pfwd1(rho^2)=3D200(0.5)=3D100w.

2. The component power transmitted through point 'x' in the direction of the source is Pref2(1-rho^2)=3D200(0.5)=3D100w.

The fields of these two component waves are 180 degrees out of phase and they are equal in amplitude so they cancel to zero. Note that Pref1=3Dzero. This is 200 watts of total destructive interference. The conservation of energy principle says that, in the absence of a nearby source (which this is), any destructive interference must be offset by constructive interference in a different direction. In a transmission line, there are only two directions, i.e. destructive interference in the direction of the source must necessarily be offset by an equal magnitude of constructive interference toward the load. That's exactly how Z0-matches function from an energy standpoint. Addition of EM wave powers are accomplished by the irradiance equation from the field of optics.

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)cos(A)

where A is the angle between the two electric fields associated with the two waves.

Pref1 =3D 100w + 100w - 200w =3D 0, where the -200w is destructive interference (negative sign).

3. The component power transmitted through point 'x' in the direction of the load is Pfwd1(1-rho^2)=3D200(0.5)=3D100w.

4. The component power reflected from point 'x' back toward the load is Pref2(rho^2)=3D200(0.5)=3D100w.

The fields of these two component waves are in phase and they are equal in amplitude so they add to double the voltage and current magnitudes. When we double both the voltages and currents, we multiply the power by a factor of four. Thus, two 100 watt waves result in a single 400 watt wave when they engage in total constructive interference as they do in the above example.

Pfor2 =3D 100w + 100w + 200w =3D 400w, where the +200w is constructive interference (positive sign).

|destructive interference| =3D |constructive interference| and all is well with the conservation of energy principle.

Note that the physical power reflection coefficient is 0.5 everywhere. However, Pref1/Pfwd1=3D0, i.e. the virtual power reflection coefficient is zero (same as the single-port reflection coefficient).

All of the power reflected from the load, Pref2, is redistributed back toward the load at point 'x', i.e. the virtual short, virtual power reflection coefficient is 1.0 even though the physical power reflection coefficient is 0.5 at point 'x', i.e. A single-port analysis yields a power reflection coefficient of 1.0 looking back into point 'x'.

Walt is obviously using a single-port analysis where *everything is virtual*. Impedances are V/I ratios, not actual devices. Thus the Pref/Pfwd power ratios are virtual. The difference between reflected energy and interference energy is the difference between real-world reflection coefficients based on real-world impedance discontinuities and virtual reflection coefficients based on V/I ratios and Pref/Pfwd ratios.

Walt, here is my humble opinion of what the problem is:

1. You are considering that virtual impedances and virtual reflection coefficients exist in reality to the point that they can be the cause of something. IMO, everything virtual is a result, not a cause. That's why it is called "virtual".

2. You are considering the redistribution of reflected power back toward the load to be 100% caused by reflections governed by reflection mechanics. IMO, that is OK for a voltage analysis, where energy considerations are completely transparent, but definitely NOT for a power analysis. When power is being considered, the difference between reflected energy and interference energy MUST be taken into account because INTERFERENCE ENERGY DOES NOT OBEY THE RULES OF REFLECTION MECHANICS. It obeys the rules of interference mechanics.

3. The assumption that all sources are non-dissipative is a convention that I was taught in college. My professor emphasized that it is a *convention*, convenient for analysis, but not necessarily true in reality. Thus it is assumed that any reflected power that is absorbed by the source was never generated in the first place. But that is a *convention* to make the math easier and not necessarily what happens in reality.

4. The V/I ratio that is your mismatched source impedance is indeed non-dissipative but is most likely a combination of reflections and interference caused by reflected energy flowing into the source and superposing with the generated wave. IT IS SIMPLY IMPOSSIBLE FOR REFLECTED ENERGY TO SIMULTANEOUSLY BE THE CAUSE OF A VIRTUAL SOURCE IMPEDANCE WHILE BEING RE-REFLECTED FROM THE SOURCE TERMINAL, i.e. it cannot be used at the same time for two completely different purposes at two different locations. Somewhere back inside the source, it is likely that dissipation of reflected energy is occurring in any mismatched system.

I have said this before and it fell on deaf ears. Since RF energy cannot travel faster than the speed of light, the only way that a source can know the value of its load impedance is in the form of feedback of *reflected energy* from the load, i.e. unless the load impedance is equal to the source impedance, REFLECTED ENERGY MUST NECESSARILY BE FLOWING INSIDE THE SOURCE FOR THE SOURCE TO DETECT THE

VALUE OF ITS LOAD IMPEDANCE. The reason for confusion about this subject is that the lumped circuit model presumes instantaneous, faster than light speed, throughout the universe. This faster than light concept is set in concrete brains throughout the RF engineering world. It is indeed strange that RF engineers using the lumped circuit model, don't realize that it takes about one ns for a source to detect a load that is six inches away. The V/I ratio from the source changes after one ns when the first reflected energy arrives. The source has absolutely no way of detecting its load impedance until the first reflected energy arrives. Any other concept is just magical thinking about the real world.

Here is a special case example where all of the steady-state reflected power is dissipated in the source resistor. This particular source was presented by w7el in his food-for-thought series.

Sorry Owen, my data above that you say is wrong is not wrong. I'm absolutely astounded that you would say so. You have misconstrued my data to make such an assertion. I calculated the data and then plotted it on the Smith Chart, which verified the data as correct.

So that other readers will understand how I calculated the data I'll begin with the 150-ohm load terminating the 50-ohm line, yielding a normalized impedance of Z =3D 3 + j0. Moving along the line toward the source the line impedance changes, arriving at a point where normalized line impedance is 1 - jX. The reactance X is determined by the SWR on the line which is 3:1. jX =3D 1/(sqrt SWR/ SWR - 1), which yields jX =3D -1.1547 ohms. This value of jX is verified by drawing a radial of 3:1 SWR to intersect the unit-resistance circle on the Smith Chart. By inserting an inductive reactance jX =3D +1.1547 ohms in series with the line at this point cancels the line reactance, making the normalized line impedance 1 + j0, where it was previously 1 - j1.1547.

Inserting the inductive reactance at that point causes a discontinuity in the line that generates a second reflection, a canceling reflection that cancels the primary reflection, thus establishing an impedance match at that point.

Now where is the impedance-matching point on the line? First we find the voltage reflection coefficient of the normalized impedance at that point, which is rho =3D (Zo - Zx)/(Zo + Zx) =3D 0.25 - j0.43301, which when converted to polar form, rho =3D 0.50 @ -60=C2=B0. Extending the radiu=
s

through the 3:1 point on the unity-resistance circle on to the
periphery of the Smith Chart, it lands on the -60=C2=B0 point, which again
confirms the validity of my data that you assert is wrong.

Owen, you are a brilliant and an excellent lecturer. But I don't
believe I need a lecture on impedance matching with transmission
lines. So just on one point, where have I inferred that I was not
working in the steady state?

Walt, W2DU

I forgot to mention in the above post that the -60=C2=B0 on the Smith Chart
periphery is the angle of the reflection coefficient, which is twice
the value of the electrical length. Therefore, the matching point is
30=C2=B0 from the load toward the source.

On Jun 18, 10:49=A0am, walt <w...@w2du.com> wrote:
> Now where is the impedance-matching point on the line?

By definition, the Z0-match point is where the reflections toward the source are first eliminated, i.e. Vtot/Itot=3DZ0, which is on the source side of the inductive stub. If reflections were eliminated anywhere else (closer to the load) then there would be no need for that section of feedline. An energy analysis is possible but would no doubt be messy. For instance, what is the SWR at the stub short? Where is the ground reference at the stub short? Since the series stub is a certain number of degrees long, the two currents at the mouth of the stub cannot possibly be 100% differential, i.e. common-mode currents exist on the series stub. Since there is a phase shift in the series stub that doesn't exist in the main coax braid, common-mode current must be flowing in the rest of the system. Electrically, how long is the series stub in degrees? Does an impedance discontinuity exist at the short at the end of a series stub like it does at the end of a shorted stub - or not? What is the characteristic impedance of a series stub? (It is probably not the Z0 of the transmission line being used.)

There is obviously a multiple-port impedance discontinuity at the Z0-match point but I don't know what it is or how to measure it. I don't even know how to measure the multiple-port s11 at the Z0-match point. IMO, this example is just too complicated for 99.9% of the readers here, including myself.

If we put the series stub (or inductive coil) into a two-port black box and performed s-parameter measurements on it, we could come up with the s-parameter equations.

Source--50 ohm line--x--black box--y--150 ohm load

Reckon what s11 we would measure if we replaced the 150 ohm load with a 50 ohm resistor?

By my calculation, the normalised line resistance at that point is 1.

You acknowledge that a couple of lines later when you said "...for a line i=
mpedance of 50 - j57.735 ohms", hence my further comment to that effect.

> absolutely astounded that you would say so. You have misconstrued my

I don't think so Walt, I think you have made a typo you haven't yet seen.

Owen

That was a sidetrack, as Walt's example is a series stub and in that case, the V/I looking into the series combination is simply the sum of V/I for each.

verticals have gotten a bad rap, they are considered noisy only
because most people who don't have room for anything else put one up
on their roof or back yard where they are often near noise sources.

any dipole that low isn't going to be very directional, especially if
it is near a buiding.

no, don't transmit through the ice180, it is for receive only.

since the ts590 has a built in tuner just throw up as long a dipole as
you can fit as high as you can get it and get on the air... any
antenna is better than no antenna, and you can make a dipole as good
as any you can buy at much less cost.

...
Yep. Thanks, John. I'm not sure HOW I managed to do THAT! I thought
I copied-and-pasted, but something got messed up. Hope your revised
URL helps others looking for connector info.

Ralph: I wonder if it's a specially modified N for some weird
application. I've seen UHF connectors modified with the center taken
out so that RG-213's center conductor and dielectric can be extended,
for use in connecting high voltages. Your adapter sounds way
different than that, though.

Cheers,
Tom

Owen, are you still saying my data is wrong? And that I've made a typo
that I missed? I can't believe I'm reading this. So please tell me,
where is that typo? And please explain further where you believe I've
made an error in calculating the data--I don't think so.

And for Cecil, you're worrying about common-mode currents on my series
stubbing? I mentioned in a earlier post to not worry about it, because
my series stubbing was used only as a tool to explain how the
canceling wave is formed, and was not intended as a practical
procedure for matching a line.

This is inconsistent, if I normalise 50-j57.735 I get 1-j1.155.

The first line of the quote is correct IF you replace the work resistance with reactance, otherwise it is wrong.

Owen

Best states early in his article "In this and the two subsequent articles, =
Thevenin equivalent circuits are used in the analysis of the wave reflectio=
ns
that occur within a transmission-line system. A Thevenin-equivalent circuit=
 consists of a constant-voltage source, VS, and an equivalent series output=
 impedance, ZS. This equivalent circuit is not intended to be an accurate
physical representation of the output stages of a transmitter. However, the=
 Thevenin-equivalent circuit can be used to illustrate concepts associated =
with the wave-reflection mechanics that occur within a transmission-line sy=
stem
```

and specifically at the output terminals of a transmitter."

Whilst acknowledging that the Thevenin equivalent is not intended to be an =
accurate representation of a transmitter, he goes on to assert that it can =
be used to illustrate what happens in a network with a transmitter.... so t=
o me, it seems that the one thing that has been readily dispensed with in t=
his application is accuracy.

His equation 8 seems to me a development of why / how steady state is estab=
lished in a context where the source is validly represented as linear, one =
where Gamma is independent of V and I at its terminals.

A long time ago, I was showing people how to align microwave filters using =
Return Loss (RL) measurement as the indicator of filter response. So, we ha=
d a sweep generator (with tightly controlled equivalent source impedance of=
 50+j0 ohms), to a circulator with filter on the next port and a crystal de=
tector on the next port. The filter was terminated in 50+j0, and the filter=
 was aligned for a specified RL response over a frequency range.

I questioned in my own mind at the time whether measurement of the reflecti=
on only was indeed measuring RL, we had not proven that the forward wave wa=
s constant with frequency and load impedance. This question was answered by=
 a quite simple analysis that showed that the forward wave component wrt so=
me Zo=3DRo was constant if the source impedance was validly represented as =
a Thevenin source with source impedance equal to Zo. Since these sources ha=
ve controlled source impedance, usually by way of a large attenuator at the=
 output port, there was no need to measure the forward wave vs frequency, a=
 single measurement with the filter port of the circulator terminated in a =
s/c provided a correct baseline of RL=3D0dB for the subsequent filter measu=
rement.

Applying that knowledge to the case of a transmitter, if you were to connec=
t a directional wattmeter between a HF ham transmitter and a variable imped=
ance load (eg an ATU followed by a dummy load), and vary the load impedance=
, changes in observed 'forward power' suggest that the transmitter is not w=
ell represented as a Thevenin source with Zs=3D50+j0 ohms. In my experience=
, the results of this test vary from transmitter to transmitter, but even w=
ith a single transmitter, vary with power level, different sensitivity to c=
hanges in R and X components of load Z, and frequency.

Owen

It's an ordinary BNC to Male N adapter, where the dielectric has been somehow mangled, causing the center shield, pin, and dielectric to get pushed out. You might be able to disassemble the adapter and repair it. Try pushing on the center pin on the N side of the adapter and see if it moves back into the adapter. Some of the cheap connectors from China are little better than junk and tend to fall apart with little provocation.

Hint: Photos are useful for identifying strange connectors.

You're right about the resistance vs reactance blip. That wasn't a
typo but a thought aberration. Sorry I didn't catch it.

But no, Owen, 1.1547 is correct from the equation. Increasing to seven
significant figures it's really 1.1547005. If you set your calculator
to three significant figures and divide 57.735 by 50, you get
1.1455, true. But if you set it to five significant figures you still
get 1.15470, and you're quibbling about the round-off error? The

```
precise  figure is obtained from the equation, not off the Smith
Chart.

Walt

Ok, well whatever it was, it was wrong as I said, but you have got it now!

It was not about precision, it is not about round off errors, it is the sta=
tement that "normaised resistance is 1.1547" when it is actually 1, normali=
sed reactance though is 1.1547.

The comment was a byproduct of my reading and working through what you wrot=
e, trying to understand it.

The other thing that was mentioned in discussion is the "non-dissipative re=
sistance" which you seem to think must give rise to Gamma=3D1 at the source=
. This "non-dissipative resistance" seems an invention that is quite flexib=
le, quite convenient, because it seems that some posters regard radiation r=
esistance as a "non-dissipative resistance" yet they have not argued that G=
amma at the antenna equals 1.

Owen

For some reason, Google Groups won't let me see any postings to this
thread past June 13th. If anyone has asked me any specific questions
related to my post about that time (which I also can't see now), my
apologies for not answering. Maybe Google will fix this, but I rather
doubt it. I suppose I'm better off not knowing what all is going on
anyway.

Cheers,

```
Tom

t.net ---

Indeed, I am a brandy new Technician... I plan to upgrade to General in short order. I decided to space the tests out a few months appart as I learn. I already knew a good deal of what was on the Technician exam from my many years of sw dx'ing and homebrewing. I am also up near eight words per minute with CW, but that is only with the learning program I have been using on my PC. I never actually sent any CW :-) My plan is to get my antenns set up and try some phone on 10 meters where the Technicians are allowed with that mode. I also have a few friends in the area that are hams that I will cut my CW teeth on :-) I dont have much interest in VHF and UHF, so I have every intention of securing my General soon. My real interest is 80 and 40 meter DX. As far as the antenna goes... I've decided to string up a ladder fed diepole. Seems the best way to go for now... Later on a yagi :-)

Thanx for the response...

I actually have a 102' G5RV that I used to use for short-wave
listening. Currently, it is coiled up in storage in my basement. I
took that antenna down along with a long wire I had after I built the
inverted L that I currently use for short wave listening. The
inverted L did better across the board than those other two antennas,
so I took them down. The G5RV had a decent signal to noise ratio for
short wave, but the inverted L I built is considerably better. I'd
assume that grounding the matching transformer properly made all the
difference. At any rate... I would not used that old G5RV for my
transmit antenna because the feed line is only 300 ohms. Since I have
decided to go with a wire dipole for starters, I'm moving on now to
buy the best one I can find. I don't care to homebrew my first ham
antenna... Rather have one that I'm sure works while I'm learning the

Tom, I had the same problem and clicking on "sort by date" solved the
problem.

Since you decided to start with a wire dipole, consider making or downloading a map centered on your location so you optimize the orientation for whom you want to work. For example, my 20m Field Day dipole will be optimized for 060 degrees, the bearing from Southern California that favors the most of North America. Getting it wrong can cost more than an s-unit.

http://www.wm7d.net/az_proj/ will provide one from your inputs. (I could only get it to print North America just now; probably something I did.)

If you make a resonant dipole cut to length for one band (my preference), its height-above-ground affects its resonant frequency. Close to the ground brings resonance at a lower frequency than the formulas predict, so you'd need to shorten it to bring it to resonance (at that height).

Antennas can be hard work but when you get one that plays well, it's all worth it.

```

Here's the mathematical problem with assuming a reflection coefficient
of 1.0 at the source output: Let's assume 100 watts of sourced power
and 50 watts of incident reflected power in a 50 ohm environment.

Source Wave: V=70.7v at 0 deg, I=1.414a at 0 deg, 100w toward the
load.

Incident Reflected Wave: V=50v at 0 deg, I=1a at 180 deg, 50w toward
the source.

A reflection coefficient of 1.0 assumes a (virtual) short at the source. A short circuit reverses the phase angle of the incident reflected current during the reflection process so all forward-traveling voltages and currents would have a phase angle of zero degrees. Superposition phasor math becomes simple arithmetic addition.

Re-reflected Wave: V=50v at 0 deg, I=1a at 0 deg, 50w toward the load.

70.7v at 0 deg PLUS 50v at 0 deg EQUALS 120.7v at 0 deg.

1.414a at 0 deg PLUS 1a at 0 deg EQUALS 2.414a at 0 deg.

120.7v(2.414a)=291w, i.e. 141 watts more power than the source power and reflected power combined. Where did the extra power come from?

Conclusion: Assuming a reflection coefficient of 1.0 looking back into the source violates the conservation of energy principle. (The only exception to this assertion is the special case where the incident reflected wave arrives orthogonal to the sourced wave.)

Here's the problem with assuming that a virtual impedance can cause reflections:

A virtual impedance is created according to the following equation using *phasor math*:

Zvirtual = (Vfwd+Vref)/(Ifwd+Iref)

Note: REFLECTED ENERGY HAS TO BE FLOWING BACKWARDS THROUGH THE VIRTUAL IMPEDANCE POINT FOR THE VIRTUAL IMPEDANCE TO EXIST.

How can the same reflected energy be re-reflected while at the same time being used to cause the virtual impedance that causes the re-reflection? Isn't that akin to having one's cake and eating it too?

Don't try to read too much into the antennas. Unless you can get an 80 meter up to around 100 feet, just about any dipole will work. I like the Windom or Off center fed antenn myself for an all around antenna. It just does not work 15 meters or the WARC bands very well.. I have one up and an 80 meter dipole about the same height (about 50 feet) at right angles to it. Not much differance most of the time, but sometimes one or the other will be about 10 db beter.

For 80 meters and up, about 130 to 140 feet of wire fed with ladder line and

a good tuner is a good way to go if you want to bring the ladderline into
the tuner.

Depending on how much work it it, you may want to put up a 10 meter dipole
or if possiable make it out of aluminum conduit or such and make it so yo
can rotate it.

As you problay know there is no CW test now. You should have taken the
General written test when you took the other one. Should not have cost any
more at the time and you may have gotten lucky.

It only took me about 30 years to get my triband antenna up.. I was mainly
interisted in weak signal vhf and did have a light weight tower up about 40
feet for that, but it would not hold a triband antenna. Finally moved to
another location and put up a good tower to 60 feet with the triband and
other vhf antennas.

> 73, Cecil, w5dxp.com

The problem here Cecil, is that you've made the same error as Steve in believing that the reflected voltage adds to the source voltage at the source to establish the forward voltage. I've proven that it does not, but it's power or energy that adds. Adding the voltages gives the wrong answer--adding the powers does not. (When adding reflected and source voltages you obtain the standing wave, not the forward wave.) When you add the 50w of reflected power to the 100w of source power we get 150w. On the 50-ohm line, 150w breaks down into 86.603v and 1.723a, No extra power to be accounted for, and no violation of the Conservation of Energy Law.

The explanation of this concept appears in Chapter 25 of Reflections 3, beginning on Page 25-3, Col 2, Par beginning with "As mentioned earlier, Steve failed to recognize..." From there on into the math I present on the next page proves the concept to be correct.

Concerning 'virtual' impedances, an impedance is an impedance, whether formed by Z =3D E/I, or by a physical impedor. Virtual opens or shorts are different animals, established by two conjugately-related reflected waves traveling in the same direction, and arriving simultaneously with the source wave at an impedance matching point. Please read all of Sec 25.3 in Chapter 25, beginning on Page 25-5.

True, the thing with aioe.org is that you don't need to create a
password and no need for a real email addy, even of the throwaway kind ...

This is great in an aid of making the world wide wiretap more difficult
to track/trace you, couple that up with a phony isp number, change the
volume id only hard drive now and then, and use mac makeup to switch the
mac no. on your nic now and then and it becomes even more difficult, use
another identity to make it appear as if you are really someone else and
you start getting a bit of security ...

Really, no one should be using their real isp for usenet anyway!
Everyone should be pretending like it's 1984, which it is!

One thing most people can't appreciate the advantage of is having your
own email server. I helps a lot when you have a low bit rate connection.

I don't need lamp modules, they are less satisfactory.

Which controller do you have?

And maybe we should move this offline.

I am not familiar with EZNEC, but I would say that you must enter 2000W, simply because the RMS concept cannot be applied to power (only "average power" exists, not "RMS power").

RMS can be used for voltage or current, but not power.

So, "2kW PEP" means that the "average power around the instant in which power is maximum" is 2kW.

Probably EZ-NEC returns you the RMS V/m or RMS A/m values around the instant in which V/m or A/m is maximum.

In the ARRL Antenna Handbook it discusses feeding the Lazy H antenna. The handbook states; "Matching stubs are recommended in cases where a non-resonant line is to be used". Is the handbook referring to coax verses ladder line, is it referring to a resonant length of ladder line verses a non resonant length of ladder line, it is referring to ladder line with an antenna tuner at the transmitter verses ladder line without an antenna tuner? In any case I'm not sure what they are specifically referring to. Clarification requested please.

Thank you,

Michael Rawls

They are probably worried about losses if there is a high SWR on the coax feedline. I don't see any reason why the Lazy-H can't be fed with ladder-line and Z0-matched to 50 ohms at the tuner which will cause a near conjugate match at the antenna feedpoint and throughout the rest of the system using low-loss feedline.

A possible explanation is the following one.

If you use an appropriate matching stub at the antenna, the antenna impedance
can be made equal to the ladder line characteristic impedance. In such (matched)
condition, the impedance seen by the transmitter is independent of the ladder
line length. You will most likely need a tuner at the transmitter to adapt that
impedance to the 50-ohm transmitter impedance.

On the contrary, not using any stub, the antenna impedance will most likely be
different from the ladder line characteristic impedance. In such (unmatched)
condition the impedance seen by the transmitter varies with the ladder line
length. Trimming that length, you may obtain an impedance close enough to 50
ohm, so avoiding the need for a tuner (although a balun will stiil be needed).

Seems like it would be helpful if the handbook gave you an accurate definition of what they mean by "stub" and "resonant" versus "non-resonant" line. To me, a "stub" means a length of transmission line attached to a feed system (perhaps at the antenna feedpoint, but perhaps instead attached to the through-line feeding the antenna at some point away from the antenna feed point), which is open or shorted at the free end. (It's also possible to have a stub that's tuned by putting a [variable] capacitance across the free end--or an inductance.) That is, a "stub" is NOT a piece of transmission line in series with the feed line (which makes it a part of the feed line). If you have a piece of transmission line feeding the antenna whose job it also is to transform an impedance, it _might_ be called "resonant," though I would much prefer the term "series matching section" of line. That's because, in general, the length might not be an integer number of electrical quarter waves. The series section might be used to tune out reactance as well as transform the resistive part of the impedance.

So my suspicion is that they are using "resonant line" to mean a "series matching section," where the series matching section is (probably) an odd number of quarter waves long, to help match between two different resistive impedances. The ideal impedance of that series section would be the square root of the product of the two impedances (resistances) you want to match between.

I use a program called "winSMITH" which I love because it lets me very quickly see what pretty much any arbitrary "ladder" arrangement of line sections (series and stub)--as well as lumped reactances--will do to transform any arbitrary impedance. The graphical representation gives me insight into what's going on, and how I can adjust things to get the best match. Though I especially like some of the features of this program, there are other Smith chart programs that will give you similar insights. Several of these programs are free. It takes a bit of playing with them to understand what's going on, but I think it's well worth the time because of the deeper understanding you'll get from them. "YMMV" as they say; if graphs don't do anything for you, a Smith chart probably won't either.

Cheers,
Tom

I have added a further update to the AIM4170 Presentation, showing a TDR scan on an open-wire feeder.

Go to: http://homepage.ntlworld.com/wadei/aim4170.htm

then click on the link "AIM4170 PowerPoint Presentation".

New slides 72, 73 and 74 show clearly that although Zo = the calculated free space value at the antenna feedpoint, it is otherwise considerably affected by the feeder’s proximity to ground and other objects.

Zo actually falls as the feeder descends from the shack window to the garage, remains more-or-less constant as it passes over the garage roof, and only begins to increase again as it traverses the hedge and passes through the tree. Note also that the impedance decreases slightly where the feeder narrows at the antenna feedpoint.

Yet another example of the incredible versatility of the AIM4170.

K8JS was correct about the factory balun in the Dentron MT-3000a not working correctly on 10 meters (see below). I by-passed the built in balun by using a 3 foot jumper out one of the other antenna coax jacks and then connecting the 450 ohm ladder line to the external 1:1 balun. The Lazy H antenna lit up! Now it is performing like I was expecting, and the missing gain is definitely there. I initially tried an external 4:1 balun, but since I had previously trimmed the 450 ohm ladder line to get a better match to the tuner I wound up getting a better match with an external 1:1 balun. Now I need need to replace the internal 4:1 balun in the Dentron MT-3000a, so I can get my open wire antenna position back.

I have to retract my previous statement when I said the Lazy H antenna sucks. They rock. It is the built in factory 4:1 balun in the Dentron MT-3000a that sucks on 10 meters. With the new balun the Lazy H antenna is performing beautifully. I already built a second Lazy H, and I have it pointing in a different direction. The side rejection on those antennas is pretty impressive, and both Lazy H antennas are now blowing away the rotatable dipole in their favored direction.

Thank for all the help,

Michael Rawls
KS4HY

Hi Michael,

That sounds good.

>It is the built in factory 4:1 balun in the
>Dentron MT-3000a that sucks on 10 meters.

It probably sucks equally on all bands.

>With the new balun the Lazy
>H antenna is performing beautifully.

It would serve us all, and specifically you, if you would describe
EXACTLY what the difference is between the factory built BalUn and
your own new BalUn.

First, can you distinguish between Voltage BalUns and Current BalUns?
They go by other names such as Ruthroff and Guanella. Can you
enumerate the characteristics beyond the transformation ratio?

Do you understand the concept of Common Mode current, and how (not how
much) it impacts performance?

I have a question for W5DXP, KB7QHC, W7ITM and K0TAR relating to
transmission lines.This is not a trick question. This is a straight-forward question for which I 'm dead serious. The answer will involve
a resulting reflection coefficient.

Assume a 50-ohm line terminated in a purely resistive 150-ohm load,
yielding a 3:1 mismatch with a voltage reflection coefficient V=F1 equal

to 0.5 at 0=B0. We want to place a stub on the line at the position relating to the unit-resistance circle on the Smith Chart. For a 3:1 mismatch this position is exactly 30=B0 rearward from the load, and has a voltage reflection coefficient V=F1 equal to 0.5 at -60=B0. The normalized line resistance at this point is 1.1547 chart ohms, or 57.735 ohms on the 50-ohm line, for a line impedance of 50 - j57.735 ohms.

Placing a short-circuited stub having an inductive reactance of +j57.735 ohms on the line cancels the line reactance, establishing a new line impedance at this matching point of 50 + j0. However, a lot more is involved than just canceling the reactances to establish the impedance match. To begin, the stub generates a new, secondary, canceling reflection that cancels the primary reflected wave generated by the mismatched line termination.

Recall the voltage reflection coefficient V=F1 of the line impedance prior to placing the stub--V=F1 =3D 0.5 at -60=B0. The corresponding curren=
t
reflection coefficient I=F1 =3D 0.5 at +120=B0

We now look at the voltage reflection coefficient of the stub, which is V=F1 =3D 0.5 at +60=B0, and the corresponding current reflection coefficient of the stub which is I=F1 =3D 0.5 at -120=B0.

Observe that resultant angle of the voltage coefficients is 0=B0 and resultant angle of the current coefficients is 180=B0, all with the same magnitude--0.5. It is well known that when these respective coefficients exist at this point, the matching point, this condition establishes a virtual open circuit to rearward traveling waves at this point, prohibiting any further rearward travel of the reflected waves, thus reversing their direction toward the load.

Consequently, the result is total re-reflection of the two sets of reflected waves at the match point.

Now the question--what is the resultant voltage coefficient of reflection at the match point? My position is that =F1 =3D 1.0, which indicates total reflection. However, I've been criticized on this value, my critics saying that because this virtual open circuit was established by wave interference, =F1 cannot equal 1.0. They assert that =F1 =3D 1.0 can be obtained only through a physical open circuit.

So I now ask you, am I correct in saying that the reflection coefficient in this situation is 1.0? I'm holding my breath for your answers.

Walt

Unfortunately, the symbol for rho came thru as 'n' with a diacritical
mark over it. That incorrect character should be replace with the
Greek symbol rho, which this venue cannot print.

Walt, some of us have previously discussed the difference between a one-port s11 (reflection coefficient) and a two-port s11 and I think that difference is what you are seeing. The one-port s11 (rho) is a virtual reflection coefficient based on the available system information. In that case, rho is 1.0. However, if we use the two-port parameters, I believe s11 (rho) will be 0.5. The matching stub complicates the analysis so maybe we can reduce the complexity using a slightly different example about which you can ask the same question and the answer will be a little easier.

--50 ohm--+--1/2WL 150 ohm--50 ohm load

It's essentially the same problem without the complexity of the stub. There is a 50 ohm Z0-match at point '+'. The one-port s11 (rho) looking into the Z0-match point from the source side is 0.0 because there are no reflections. The one-port analysis is blind to any interference that might be recognized if we were using the two-port analysis.

The one-port s11 (rho) looking back into the Z0-match from the load is 1.0, same as your virtual open/short. The one-port analysis used for your virtual open/short concept is unaware of the interference that is visible in a two-port analysis. A one-port analysis cannot tell the difference between an actual reflection and a redistribution of energy associated with superposition interference.

However, the two-port s11 (rho) looking into the Z0-match from the source side is 0.5, i.e. (150-50)/(150+50). Interference is not invisible in the two-port analysis. In fact, when the voltage reflected toward the source is zero, there is total destructive interference in the direction of the source.

b1 =3D s11*a1 + s12*a2 =3D 0

where all math is phasor math. The two terms cancel destructively to zero. The ExH energy components in those two terms are redistributed back toward the load.

In a two-port analysis, the reflection coefficient looking back into the Z0-match from the load is called s22. The matching equation is:

b2 =3D s21*a1 + s22*a2

All of the destructive interference energy involved toward the source is redistributed back toward the load as constructive interference. But such is invisible in a one-port analysis such as your virtual open/short circuit.

There is nothing wrong with your one-port virtual open/short circuit analysis. There is also nothing wrong with the more in-depth two-port analysis. It is simply that more information is available during the two-port analysis.

Over on another newsgroup, some reported using a one-port analysis almost all of the time. Tell your critics that you are using a one-port analysis where the interference information is simply not available during the analysis.

What is the one-port reflection coefficient looking into a Z0-match from the source side? 0.0
What is the one-port reflection coefficient looking into a Z0-match from the load side? plus or minus 1.0

That is what you are doing with your virtual open/short and there's nothing wrong with a one-port analysis.

Hi Cecil and Richard,

Thank you for the insightful response, Cecil. However, when you go to the 2-port version I=92m unable to correlate that configuration with my stubbing problem.

Here=92s what my problem really involves. Referring to Eq 8 in the first part of Steve Best=92s three-part article published in QEX, the equation is as follows: The section within the parentheses is the voltage-increase factor when all reflections have been re-reflected. That section is 1/1 - (rho_=92a=92 x rho_=92s=92), where =91a=92 is the mismatch= at the antenna (the load) and =91s=92 is the mismatch at the source.

We=92re considering the source to be an RF power amp, where we know the output source resistance is non-dissipative, thus re-reflects all reflected power incident on it. I maintain that the reflection coefficient at the source is 1.0 because of the total re-reflection there.

Now consider working with the output of the pi-network of the RF anp, where I believe the reflection coefficient is 1.0, and the 3:1 antenna mismatch that yields a reflection coefficient of 0.5. Plugging these coefficients into the equation section yields 1/1- (1 x 0.5), which equals 2.0, which is incorrect, making that equation invalid, IMHO.

The correct value with these coefficients should be 1.1547, not 2.0.

However, mathematical experts say that the equation is correct, saying
that rho_=AC=92s=92 cannot be equal to 1.0, because the virtual open circui=
t
was established by wave interference, not a physical open circuit.

The reason that I didn't say anything about the stub example is
because I cannot comprehend it without a schematic. That's why I
changed examples. Do you agree with what I said about my example?
Could you post a schematic of your first example? It is the "series
stub" part that I don't understand. Such is usually called a "series
section" because a stub is usually a parallel dead end open or short

```
circuit. It is also difficult to comprehend how a two-port analysis
could be done at the stub connection point. Wouldn't that require a
three-port analysis?

How's about we limit the *initial* discussion and examples to a source
with zero incident reflected power so the source impedance doesn't
matter? IMO, a two-port analysis of a Z0-match point will reveal the
main ingredients of the energy flow.

> However, mathematical experts say that the equation is correct, saying

uit
> was established by wave interference, not a physical open circuit.

A one-port analysis cannot tell the difference between wave
interference and reflections. You are correct that the reflection
coefficients are not necessarily the same between a one-port analysis
and a two-port analysis. Your "mathematical experts" don't seem to
understand the limitations of a one-port analysis. It's akin to not
knowing what is inside a black box, i.e. one cannot tell the
difference between a resistor and a virtual resistance. However, with
a two-port analysis, one can tell the difference. It appears that your
"mathematical experts" are insisting on a two-port analysis such as
provided by the s-parameter equations:

b1 =3D s11*a1 + s12*a2

b2 =3D s21*a1 + s22*a2

Cecil, the series stubbing appears in Reflections, Chapter 23, with
the same values as I presented above, with detailed diagrams shown in
each step in the progression of the explanation. I hope these diagrams
can help.

As I said in the previous post, the experts were referring to the
output of the RF amp as not establishing a reflection coefficient rho
=3D 1.0, which has put me in a corner.

Sorry Cecil, I can't correlate a two-port configuration using S
parameters with the problem I have. Thanks a million for the
discourse.

Walt

The corner I'm in, Richard, is that In Reflections 3, Chapter 25, I assert that Steve Best's Eq 8 in the first part of his three-part article appearing in QEX is invalid, because it gives incorrect answers when I plug in what I believe are correct values of reflection coefficients. Yet his equation agrees with that of Johnson on Page 100 of his "Transmission Lines" text book. In addition, a mathematics expert whom I respect says Best's equation is correct. So I've got to make the decision whether to delete my criticism of his equation or leave it in and be accused of criticizing him incorrectly. What to do!

Walt

Hi Walt,

So this is not only double-deep, through your work to Steve's, but triple deep then through Steve to Johnson.

Lacking the necessary, culminating edition of Johnson's, I still don't know what the corner is.

Lacking the complete math from all sides of the argument (not somewhere I would like to go), and noting that many authors (not making attributions here) frequently ignore some relatively basic mandates where they don't matter, to then expand into situations where they do matter; then I don't really trust heavily editorialized math analysis.

I note your summary statement for Steve that you find contentious, viz.

    "A total re-reflection of power at the match
    point is not necessary for the impedance
    match to occur."

is one where I would agree with Steve; but not necessarily for reasons brought forward. What is worse, this simple statement may mean three things to two people.

I'm surprised that there were no FUs to this (at least in ukra).

This looks like a seriously useful bit of kit for the antenna experimenter, but whether I could personally justify one for my string-and-sealing-wax approach to short wire antennas is questionable.

Although this device means one could fine-tune one's antenna, the one thing that affects very nearly every Amateur is the ground around their installation, probably up to 10 lambda before the various fields and rays begin to sort themselves out. There seems to be no equivalent piece of kit that would enable such an assessment to be made or its effect on the station's performance to be estimated. I guess most of us take the view that one lives with what one has, and can't do much about it anyway.

I had a quick look at this piece of equipment, but couldn't see it
offering anything more than the MRS MiniVNA, which is a two
port device and a more versatile instrument.

(A one port device is useless for setting up filters etc.)

Yes, it's about that. My bit of Bedfordshire is so dry at present that I reckon the ground conductivity will be so low that I'm going to have to put down a ground mat/radials rather than try to get ground spikes down into the damp sub-soil.

And it's a bit more future proof since it has a USB connection rather
than RS-232.

I don't think RS232 is going to die just yet.

It's still easy to cater for, but as you say, USB
is a lot more convenient since just sbout every PC
these days has them.

However I'm always cautious about anything software
driven becoming obsolete.

Hence I also keep a Palstar ZM30 around for HF work,
that doesn't require a PC, but still gives me all the relevent
data for antenna work.

And after all that, I still insist on a final tune up with a
field strength meter ;-)

The mini VNA being a two port device is great for making high/low
/bandpass./notch filters and instant seeing the response.

You can line up IF xtal filters etc. Very versatile.

Thoughts on voltage vs power, reflection vs interference:

What most RF people do is deal exclusively with voltages. Power is considered only at the beginning and end of a voltage analysis, NOT during the voltage analysis. If joules/second are to be tracked seamlessly throughout the analysis, a working knowledge of the effects of superposition/interference is absolutely necessary. Optical physicists do not have the luxury of working exclusively with voltages, as we do in RF, so they must necessarily understand superposition/interference and be able to track every component of irradiance (power density).

I took a look at Johnson and he is dealing with voltage, not power, and certainly not with dissipationless resistances as part of the generator source impedance. He uses 'k' sub-script 'g' as the symbol for the voltage reflection coefficient. I'm going to use 'rho' for his 'k' with braces {g} indicating subscripts. His *voltage* reflection coefficient at the generator is:

rho{g} = (Zg-Z0)/(Zg+Z0)

which is just standard *voltage* wave reflection mechanics. What happens to the energy (power) in superposed waves is completely transparent when superposing voltages. For instance, let's say we have two 200 watt waves in a 50 ohm environment which makes each of their voltage magnitudes equal to 100 volts RMS. The electric fields of the two waves are 120 degrees apart. What happens when we superpose 100 volts at +60 degrees with 100 volts at -60 degrees?

Every student of three-phase power systems knows the result will be 100 volts at zero degrees. All is well until we take a look at the energy in those two superposed waves. Each wave is associated with an ExH amount of power, V^2/Z0=200w, for a total of 400 watts in the two waves. The resultant (total?) superposed wave contains 200 watts of ExH power. Most people don't give this idea a second thought but where did the other 200 watts go? To answer the question, one must understand destructive/constructive interference. In the above example, there is 200 watts of destructive interference present so the resulting "total" voltage is not the only component of superposition.

If the above occurs in a transmission line, the amount of destructive interference energy that is lost in the direction of superposition, e.g. toward the load, is redistributed in the only other direction possible, i.e. toward the source. There is a second 200w wave generated that travels toward the source but that fact is not covered when voltage superposition is involved. Note that it is a reverse-traveling wave but it is technically not a reflection of a single wave as it is the result of superposition of two waves.

Voltage superposition takes care of itself and everyone believes in the conservation of energy principle which is probably why very few people ask, "Where does the power go?" It is only when we are trying to track energy throughout the system that we are forced to understand the effects associated with interference.

Thoughts on one-port analysis vs two-port analysis.

Sources are necessarily treated as single-port devices. We know we often get completely different reflection coefficients when treating something as a single-port device vs as a dual-port device. For instance, most of us treat a dipole feedpoint as a single-port device when it is actually far from being a single-port device. In reality, many other things besides a single reflection, are happening at a dipole's feedpoint. The actual physical reflection coefficient at the feedpoint of a "50 ohm" dipole fed with 50 ohm coax is around 0.845 because the characteristic impedance of a #14 wire 30 feet above ground is around 600 ohms. Proof: Eliminate the reflections from the ends of the dipole by terminating the ends of the inv-V dipole to ground through 600 ohm resistors and the SWR on the 50 ohm feedline goes to 12:1.

Because of reflections from the ends of the dipole, a lot of interference is happening at the feedpoint which results in a *virtual* reflection coefficient of 0.0 only because of the single-port analysis that is ordinarily used. IMO, a virtual reflection coefficient is a *result* and cannot cause anything including reflections. IMO, only physical reflection coefficients, i.e. physical impedance discontinuities, can *cause* reflections. Much of what we consider to be reflections are the result of interference.

Seems that something similar, but more complicated, is happening inside a source where there is an active-source component in the mix. IMO, what is happening to the energy inside a source cannot possibly be understood without taking the effects associated with interference into account.

Walt,

I've gotten confused here...I see in your follow-up posting that the "stub" is to be in series with the line, but you also talk about a shorted stub. It doesn't make any sense to me to put a shorted section of line in series with another line, so my confusion starts. Next, I'm assuming that we're talking about lines with real (non-reactive) impedance, so I'm wondering why you go 30 degrees from the load to a point where the reflected impedance is, as you say, 50-j57 ohms. I'm assuming we want to get to 50 ohms, eventually, and the series section to do that from this 50-j57 ohm point would have to have infinite characteristic impedance. Why not just start from the load and use a line whose impedance is sqrt(150*50) and is 1/4 wave long? That seems a no-brainer.

Or, if you want to use 50 ohm lines, go 60 degrees from the 150 ohm load and tap into the line with a shorted _stub_ (not series line section) that's about 40 degrees long, and you have your match to 50 ohms.

But of course, you're not necessarily looking for a straightforward solution to a matching problem here, you have a question about reflection coefficients. Since I got confused about just what the configuration really is, I didn't even try to sort out the rest of the posting about reflection coefficients, and I'm afraid I thus can't offer an answer to your ultimate question. I will say, though, that in a (theoretical, since lossless is assumed) system of TEM lines having real (non-reactive) impedances and loads that don't generate power, you can have any reflection coefficient magnitude from zero to unity. If you have dissipative loads, the only way you can get to unity reflection coefficient magnitude is to arrange the lines to prevent any power actually being dissipated in any of the loads: e.g., shunt the loads with shorts, or put opens in series with them.

Cheers,
Tom

Tom, I didn't know initially that the example was in "Reflections
III". A series stub can be used instead of a loading coil on a wire
antenna. I had never seen a series stub used in such a manner on a
transmission line and that's why I was confused. I'm assuming that the
center conductor is broken and one side is connected to the inner
conductor and one side is connected to the braid on a stub, but I am
not sure that is correct. There's got to be a less complicated example
that we can use.

Thanks John, I can't help but point out that such a "series stub" unbalances the transmission line currents resulting in common-mode currents on the outside braid and is probably a deviation from the original design specifications. There has got to be a simpler example that illustrates the question/answer. I thought I had it with my Z0-match example but maybe not.

Thanks John, but I would like to see the schematic for coax. Shirley,
one doesn't cut the braid and add a stub?

Thank you for the response, Tom, but apparently you're not familiar
with series stub vs parallel. You are correct that going 60=B0 from the
load is the location for a parallel stub to obtain a line impedance of
50+j0 ohms from the stub to the source. That location is the second
time you pass the unity-resistance circle on the Smith Chart, only
this second time it's the unity-conductance circle. Either method of
stubbing works. The first time the unity-resistance circle is reached
with a mismatch of 3:1 at the load is 30=B0, where the reflection
coefficient rho =3D 0.5 @ -60=B0. The normalized line impedance at that
location is 1 - j1.1547 chart ohms, or 50 - j57.7 ohms relative to Zo

=3D 50 ohms. A shorted stub in series with the line at that location of length that will derive a normalized inductive reactance of +j1.1547 generates a secondary reflection that cancels the load-generated reflection. The voltage reflection coefficient of the stub is 0.5 @ +60=B0, the opposite of the voltage coefficient of the line at that location. In addition, the current reflection coefficient of the line at that location is 0.5 @ +120=B0, while the current reflection coefficient of the stub is 0.5 @-120=B0.

Consequently, the resultant voltage coefficient is 0.5 @ 0=B0 and resultant current coefficient is 0.5 @180=B0. When these specific coefficients occur at the same location, a one-way virtual open circuit is established that prevents any further rearward travel of the reflected waves, but reverses their direction to forward, and in phase with their respective voltages and currents delivered by the source.

The problem I'm having is where the canceling reflected wave is established either by the antenna tuner, or the optimum tuning and loading of the pi-network tank circuit of the RF amp. We know that the canceling wave in the tuner occurs at its input terminals. However, many are uncomfortable in thinking of the output source resistance of the pi-network tank circuit as being non-dissipative (which it is), and thus re-reflects all reflected power incident upon it, and therefore, IMHO, the reflection coefficient of both the antenna tuner and the tank circuit is rho =3D 1.0.

My problem is in using Eq 8 that appears in Part one of Steve Best's three-part article in QEX on wave mechanics. The simplified version of Eq 8 is: 1/1-(rho_s x rho_a), where 's' =3D source resistance of the tank, and 'a' =3D mismatch at the antenna-feed line junction.

Mathematicians say Eq 8 is ok, and it does agree with Johnson on Page 100 of his text Transmission Lines. However, when I plug in 's' =3D 1.0 for the total re-reflection at the tank, and 'a' =3D 0.5 for the reflection at the antenna-feed line junction, Eq 8 delivers a value of 2, which is incorrect--the correct value is 1.1574, the voltage-increase factor when all reflected power is re-reflected with a 3:1 mismatch.

In Reflections 3, Chapter 25 I stated that Best's Eq 8 is incorrect, based on my calculations. However, mathematicians whom I respect say I'm wrong. Evidently, I'm going to have to delete that portion of Chapter 25 to avoid having readers view incorrect information. What's going on here?

Tom, if you have the time and the inclination to review this post, I'd be grateful for your opinion on whether the non-dissipative tank circuit can have a reflection coefficient of 1.0.

In a one-port analysis, virtual impedances cause reflections. In a two-
port analysis, only physical impedance discontinuities cause
reflections. As I see it, that is the entire problem in a nutshell.
You are using a one-port analysis for virtually :-) all of your
analyses, including your source analysis. Your detractors are trying
to talk you into using a two-port analysis.

Cecil, as I said earlier, I can't see any relation between a two-port
configuration and the tank circuit of an RF power amp. Why are you
pushing it? Can't you just tell me whether you agree that the
reflection coefficient at the output of the tank circuit is rho =3D 1.0
```

or not. If you don't believe it does, even though it re-reflects all
the reflected power incident on it, then please explain what you
believe the reflection coefficient is at this point.

Walt, W2DU

Ah, OK. Now I understand what Walt meant... Though it's possible to use a series stub on a transmission line, as you say, it's not all that common in practice. I suppose that's why my mind wasn't going there. Mea culpa. Perhaps now I can go back and look at Walt's original question and make more sense out of it.

When a series stub is used in an antenna (as in a quarter-wave stub coupling colinear half-waves), King points out that coupling from the antenna fields to the wires in the stub, when the stub is an open-wire line perpendicular to the axis of the half-waves, is an important factor in how the stub operates to establish in-phase currents on the adjacent half-waves... I see you made a comment about antenna currents on the stub in John Smith's example, too.

Cheers,
Tom

OK, now that I understand the series stub configuration, I have to ask: "the" reflection coefficient looking into WHAT? Looking back toward the source in its feedline? Looking back toward the source but including the series stub? Looking toward the load, including the series stub?

The way I look at this problem is as a measurements person: once I know where I'm looking, how will I measure the value of the reflection coefficient? The way I would normally do it is with a network analyzer. If I want to do it in the presence of significant power coming from a source, I can set up directional couplers to allow me to introduce a test signal (that I must be able to distinguish from the power coming from the source) and observe the reflection.

You can also replace each piece of transmission line (including the piece that's the stub) with an S-parameter two-port, and the source and load as S-parameter one-ports, and apply standard S-parameter math to see what the reflection coefficient is looking into any particular port.

I suppose this is going to give you an answer different from the one you're hoping for...but I believe it's consistent with the definitions for linear system analysis that I've always used.

Consider the case of two identical sources generating the same signal but 180 degrees out of phase. Each source is connected to a length of transmission line, and the two lines are identical. Just for fun, the line impedance equals the source impedance. The free ends of the lines are connected in parallel and to a resistive load. Of course, we find that the signals cancel and there is no power dissipated in the load. Would we say that the reflection coefficient magnitude looking back into either line toward the source is unity? I would not! I would say it is zero, since any signal I send in that direction is absorbed in the source. Note in this example that you can disconnect the load and not change anything. Then you simply have the signal from each source traveling to the other source and being absorbed; if you put the sources on two different frequencies, you'll see no standing wave for either frequency (though you'll have to average for a while to be sure about that, if the frequencies are close together). And note, please, that "absorbed" is not in general the same thing as "dissipated."

Cheers,
Tom

Personally, I didn't find anything wrong with parts 1 and 2. It's in
part 3 where Dr. Best gets lost. In an exchange on this newsgroup
before the article was published, he asserted that there was no
interference occurring at an impedance discontinuity on a transmission
line. When he published his component powers, he took into account
P1and P2 while completely ignoring (what I have dubbed) the component
powers, P3 and P4 in the opposite direction. He even invented
something like two phantom waves traveling forever in the direction of

total destructive interference while transporting energy but
completely canceling each other in the process, obviously a physical
impossibility.

Tom and Cecil,

My use of the series stub wasn't meant to be of practical use. I used
it only as a tool to explain a simple matching procedure. I used
series rather than parallel, because I wanted it to be simple to use
for those who are not as accustomed to admittance procedure as they
are with impedance. Sorry if I misled you.

Walt

I'm sorry to have misled you in bringing up the series stub problem.
```

What I'm really concerned about is the reflection coefficient at the output of the tank circuit of the RF power amp. Being non-dissipative it cannot absorb the reflected power, so it must re-reflect it. Therefore, my position is that its reflection coefficient rho =3D 1.0, My critics say that a rho =3D 1.0 cannot be established when the virtual short is caused by wave interference. However, if Best's Eq 8 is valid, then why does it yield an incorrect answer when I plug in rho s =3D 1, and rho a =3D 0.5, which gives 2 as the answer, instead of the correct 1.1547 as the correct answer.

Now that I've narrowed the problem down, what do you believe is the answer? Your answer will determine whether I need to delete the pertinent paragraph from Chapter 25 in Reflections 3, in which I have declared Best's Eq 8 invalid.

Walt

thanx for all the input... when i went to take my technician exam, i
got through it very quickly... they graded it and asked if i wanted
to take the general exam also... since i had only read the technician
manual, i did not take the ve up on his offer to try the general... i
plan to get the new 2011-2015 general manual and upgrade in the next
few months... in the mean time, i have to work out equipment and set
up issues.   i've decided on what radio to get (TS-590s) and going
with a wire dipole... the next issue is earth ground and lightning
protection. my shack is on the second floor of my house. in order to
deal with rf and lighting with my short wave set up, i went with an
inverted L that is grounded to an 8 foot brass rod through the
matching transformer. i dont have any rf problems with this set up
even though my radio is not grounded in the shack. for lightning
protection, i disconnect my coax feed and hang it out the window when
I'm not using the radio.   i've already read a pile of stuff on line
already about other people that have had the same problem with a
second floor location, but I'm still not sure what I'm going to do
about grounding the transceiver when I hook it up to a dipole.

Best says at p5-6 of his first article "In all transmission line systems, t=
he level of voltage or wave reflection at either end of the transmission li=
ne is determined from the reflection coefficient of the impedance terminati=
ng the transmission line. The =93re-reflected=94 voltage, VRER, adds to the=
 initial forward-traveling voltage, VI, and the process of reflection and =
=93re-reflection=94 continues until equilibrium is reached."

In my view, his statement is incomplete, he does not address the response o=
f the source to the new V/I ratio that exists at its terminals when the ref=
lected wave arrives and is "re-reflected".

As I explained earlier in this thread, if Zs=3DRs=3DZo=3DRo, (proof at http=
://vk1od.net/transmissionline/VSWR/Zs50.htm ) then the forward voltage comp=
onent remains constant and so, reflected voltage can simply be added to the=
 forward voltage to find the new terminal voltage.

Taking the case of a Thevenin source where Rs=3D0, terminal voltage V is co=
nstant and so Vf must change when the reflected wave arrives at the source,=
 and so Vf is not independent of Vr and so we can say that Vf is not indepe=
ndent of Vr for all Zs, but for the special case Zs=3DRs=3DZo=3DRo discusse=
d in the previous par, it is.

When Best considered the case where Gamma at the source was not 0, then he =
needed to also consider the source response to the change V/I after the ref=
lected wave arrived at the source. Best does discuss this response of the s=
ource to changing V/I in the second article where his SPICE model shows wha=
t is happening.

Discussing Thevenin sources driving transmission lines is quite interesting=
, but it is naive to think that typical RF power amplifiers response to ter=
minal V/I is the same as a Thevinin source. In any event, this is an explan=
ation of how the steady state is established rather than an analysis of the=
 steady state.

What you seem to be saying is that the voltage reflection coefficient is NOT the square root of the power reflection coefficient since if the power reflection coefficient is 1.0, the voltage reflection coefficient would also be 1.0. It seems that would be a violation of reflection mechanics. Is reflection mechanics wrong or did you misunderstand what I (and Steve) are saying?

Walt, I believe we have proven the same thing. But neither Steve nor I believe that the reflected voltage adds to the source voltage at the source. We had this same conversation years ago when I lived at my last QTH and you still seem to be confused about what Steve was saying.

Steve's P1 is *NOT* the source power (as you seem to believe). It is the source power that is transmitted through the impedance discontinuity, i.e. Pfwd1(1-rho^2). His P2 is *NOT* the reflected power (as you seem to believe). It is the reflected power that is re-reflected from the impedance discontinuity, i.e. Pref2(rho^1). It seems you have never understood what Steve was saying. Let's go over it again. The power reflection coefficient at point '+' is 0.5 looking in either direction.

100w Source--50 ohm--+--1/2WL 291.3 ohms--50 ohm load

On the 50 ohm line, Pfwd1=3D100w and Pref1=3D0w

On the 291.3 ohm line, Pfwd2=3D200w and Pref2=3D100w

Steve's P1 equals Pfwd1(1-rho^2)=3D100w*0.5=3D50w

That's the component of source power that makes it through the impedance discontinuity.

Steve's P2 equals Pref2(rho^2)=3D100w*0.5=3D50w

That's the component of reflected power that is re-reflected from the impedance discontinuity.

The total forward power on the 291.3 ohm feedline then becomes:

Ptot =3D P1 + P2 + 2*SQRT(P1*P2)cos(0)

Ptot =3D 50w + 50w + 2*SQRT(50w*50w) =3D 200w

And that is indeed the forward power on the 291.3 ohm line.

Please go back and read what Steve said given that his P1 is NOT the source power and his P2 is NOT the reflected power. His power equation comes directly from any optics physics book and is the irradiance equation for EM waves.

Steve did indeed make some errors in part 3 of his articles but the above is not one of them.

Using a dipole, which is a complete antenna, there
is no need to have an RF ground. And no need to ground
the radio, unless there is a high voltage safety reason
for it. "safety ground". But any outlet with a ground
pin will provide that.
With the case of the Kenwood 12v rig, that is not
the case. Only the power supply that feeds it needs a
safety ground. And most all those have a third ground pin
on the plug.
But you do need to worry about lightning. But less with
a dipole, than a vertical that is on the house.
The horizontal wire will be less likely to stream than
a vertical. So less likely to attract a strike.
But it can still happen. It would be best to run the
feed line straight down to ground, and then under or
along the ground to the shack. But this is kind of
impractical with a typical ladder line setup. :(
The worst case for damage is to have the feed line
running elevated in the air to the 2nd floor shack.
So if you have to run it like that, you sure don't

want it connected when storms are in the area.
I'd have some way to totally disconnect it from
the house on the outside when not in use.

This is one reason why I generally prefer coax.
Easier to mitigate the effects of lightning..
I can snub lines to ground at the base of masts,
connect and snub through a "ground window" at the
entrance to the shack, and generally it's easier
to use the typical lightning arresters.
Ladder line is harder to deal with in these aspects.
Or at least to me..
But you can use gas tubes on each conductor, etc..
That would require a good lightning ground outside.
And all grounds outside should route to a central
point, and be tied together to keep all at the same
potential.
If you use a mast to support the apex of the dipole,
it's more likely to be struck than the wire antenna
itself. So it's best to use a metal mast that is
grounded at the base. I don't use any non conductive
masts here.
I have no RF ground in the shack. Except for rare
cases, I don't believe in them. I've found they
usually cause more problems than they solve.
These problems would usually rear their ugly heads
when I would kick in some RF horsepower.. What is not
yet a problem at 100w, can be a real pain at a KW+.

I am restricting that unnecessarily, the requirement is just that Zs=Zo.

More of than not, an instrument that we might use is calibrated for some real Zo, ie Zo=Ro, and so that would mandate that Zs=Rs to observe constant Vf with such an instrument.

Thanx for the input... One of the reasons i was considering an OCF dipole over a ladder fed "ballanced" dipole at first was a matter of lightning protection. With an ocf dipole, i can use 50 ohm coax as the feed line. not to much trouble to use a gas tube. Though, i'll probably stick with my current method and just disconnect the feed line and hang it out the window even if I use an arrestor. i'm also told by a few other people that putting a sharp 90 degree bend in the feedline outside the shack is an old trick that usually helps in the case of a direct strike. i'd gather that static coming down the feedline would probably be the more common worry.

For a voltage analysis, one doesn't need to use power (or energy) at all. Given the proper voltage reflection coefficients, the voltages simply phasor add up to the proper values. The conservation of energy principle is completely transparent during the superposition of voltages. It is the power (energy) analysis that is causing the problems.

Walt, you may be right about reflected power incident upon a source being 100% redistributed back toward the load but it is definitely not due to 100% re-reflection. In any power (energy) analysis, interference effects must be included in the analysis. If the source completely rejects incident reflected energy, it is because total destructive interference is occurring within the source which results in constructive interference toward the load. Here's a reference from my "Worldradio" energy article that explains the interference phenomenon.

"[8] Maxwell, Walter, Reflections II, (c) 2001 Worldradio Books, ISBN 0-9705206-0-3 page 4-3, "The destructive wave interference between these two complementary waves ... causes a complete cancellation of energy flow in the direction toward the generator. Conversely, the constructive wave interference produces an energy maximum in the direction toward the load, ..." page 23-9, "Consequently, all corresponding voltage and current phasors are 180 degrees out of phase at the matching point. ... With equal magnitudes and opposite phase at the same point (point A, the matching point), the sum of the two (reflected) waves is zero."

i.e., a source doesn't have to have a power reflection coefficient of 1.0 in order for 100% of the incident reflected energy to be *redistributed* back toward the load. If total destructive interference is occurring within the source, the power reflection coefficient can have any value between 0.0 and 1.0.

Consider a Zg=3D50 ohm source driving a Z0=3D50 ohm 1/4WL ideal shorted stub. The voltage reflection coefficient looking back into the source is 0.0 so the re-reflected power is zero. However, zero power is being sourced because total destructive interference is occurring in the source. All of the reflected power is redistributed back into the stub by destructive interference and none of it is re-reflected, i.e., the power reflection coefficient looking back into the source is 0.0 because Zg=3DZ0.

On 6/19/2011 8:10 PM, Michael wrote:
> Thanx for the input... One of the reasons i was considering an OCF dipole over a ladder fed "ballanced" dipole at first was a matter of lightning protection. With an ocf dipole, i can use 50 ohm coax as the feed line. not to much trouble to use a gas tube. Though, i'll probably stick with my current method and just disconnect the feed line and hang it out the window even if I use an arrestor. i'm also told by a few other people that putting a sharp 90 degree bend in the feedline outside the shack is an old trick that usually helps in the case of a direct strike. i'd gather that static coming down the feedline would probably be the more common worry.

Nobody seems to have asked the burning question that's really important... what's your budget?

As far as kind of antenna, feedline, etc.

You're not going to have an optimum on all bands. For right now, as the sunspots are coming up, the high bands seem to be working fairly well (and as a Tech, all you get is 10m anyway, as far as phone.. but when you get your General or Extra, you'll get the rest.. study and take that test..)

I'm a huge fan of autotuners *at the feed*. You don't have to spend your time trying to adjust the antenna, or worrying about feedline loss, or any of a zillion other things. Sure, there's some loss in the tuner, but it's pretty easy to get the antenna close, and if the antenna is "close" then the autotuner takes care of the rest.

Life is too short to try and prune radials for resonance, and then have it go out of tune when the tree next to the antenna grows, etc.

Folks who have tube amps have the tuner built into to the output network, and they're used to the whole thing of tuning every time they change frequency, so for them, open wire line to their rig is fine. Do the match at the amp end, the loss from mismatch in the line is small because the line is high Z, etc. But that's not typical of a "brand new" station: solid state 100W amp, coax feed, etc.

My own preference is for an autotuner at the feedpoint of some sort of dipole or inverted V. Any of the 10-15-20-40 multi wire band dipoles will work quite well, and with an autotuner, you don't have to worry about "pruning to exact length". The two sides don't have to be equal length, even. Be aware that not all tuners can tune all impedances, and you generally do NOT want a transformer between antenna and tuner (esp if there's a lot of reactance to tune out), so going too far in the OCF direction may be counter productive. Then you can feed with coax, which is a whole lot more convenient than any sort of open wire line.

Second choice which is less visually obtrusive is some sort of vertical with an autotuner at the base and an adhoc counterpoise of random length wires. Higher the base, the better, in general.

Lightning protection..

Where are you located? A lightning alley like mid Florida? Or somewhere were lightning is an unusual thing (like Southern California)?

Gas tube arrestor is a nice idea. What will you hook the ground on that arrestor to? A stake pounded in outside where the coax comes in? Make sure that you run a bonding wire from the stake to the electrical system ground. A concrete encased grounding electrode is even better (Ufer ground)

Or, if you're not really in a big lightning area, just use the arrestor as a "receiver input overvoltage protector", for whatever good it might do. (I don't know what a TS590 input looks like, but the couple hundred volts from the arrestor might blow it up...). disconnect the coax when your not using it. BTW, short the coax with something and make sure it's not close to something that might catch fire if you do get a lightning hit.

The 90 degree thing is useless.. there's no significant impedance in a 90 degree bend. If you get a direct hit, unless you're spending a fair amount of time and effort on a good system, you're going to get damage..You don't want to spend thousands of dollars on a lightning protection system to protect a 1000 dollar rig.

Static discharge *is* a problem.. but, if you hook the shield to the third wire ground (or that other grounding system), on a dipole, that pretty much takes care of it. Maybe a 100k resistor between the legs (or between the vertical and ground).. Once the center insulator gets a bit grungy, leakage resistance will solve that problem for you.

e
> were lightning is an unusual thing (like Southern California)?

im in the northeastern most corner of NJ. not exactly lightning
alley, but we get storms regularly. about five years ago, one of my
radios got fried. i almost always remembered to disconnect my coax
and hang it out the window, but the one time i did not, i paid for
it. an icom pcr 1000 was left connected to my antenna switch during a
storm. i did not even think about it until a few days later, when i
went to use the radio. it powered up, but nothing else worked. i sent
it to icom and they told me it was a sure bet that static or lightning
was the culprit. since then, I have not forgotten to go through my
routine :-)

> Gas tube arrestor is a nice idea. =A0What will you hook the ground on tha=
t

That is what I had in mind. I already have an 8' brass rod in the
ground for my inverted L.

All I have to short a feed line to on the second floor is a metal
heating system radiator :-) Probably not the best choice. So... I
just let it hang out the wondow when not in use.

makes perfect sense to me... so... i have always tried to go with
"some protection is better than none". though, many are fond of
saying that "*some* lighting protection =3D zero protection"

Wimps. The antenna party barbeque is suppose to be an adventure.
Perhaps some of these would be more acceptable:
<http://vacations.com/2009/09/15/can-you-stomach-this-14-exotic-and-disgusting-entrees-from-around-the-world/>
<http://www.weirdmeat.com>
<http://listverse.com/2007/09/11/top-10-disgusting-foods/>
<http://www.manixmag.com/health-fitness/exotic-and-disgusting-food-from-around-the-world.html>

After all those, perhaps the reprocessed feces burger might look a bit
more appetizing?

One of the bad habits I acquired in my mis-spent youth was a taste for
a few bugs.
<http://en.wikipedia.org/wiki/Entomophagy>
When available, I like to munch crickets and chocolate ants.

I am telling you, I wasn't worried about much, just retired and enjoying life, but ...

Now I am back to worrying about getting some income streams going, if steak goes to $1,000 lb., I want to be able to afford the real stuff!

I don't know who they plan on eating that "SYNTHETIC MEAT" (and, I put that very, very kindly -- poor dumb japs, I think the radiation is affecting their tastes buds AND minds!), but it ain't me!

I mean, who'd a thought, they find themselves knee deep in sewage and they decide to eat themselves out of the mess! Go figure! I mean, I have to admit, that is "thinking out of the box" -- but right into the old sewer plant! EWWWWWWWWWWWWW! Kinda job security at the old food recycling plant ... you eat more, there is more waste, you eat more, more waste ...

Funny thing is, well, not really funny ... just the way that article is written is in the form of the brain washing which usually precedes the actual action(s!)

I guess I am the lightweight here, just the thought and reading that article made me gag ... I thought it would provoke more anger in Americans ... I mean, if you don't get angry about people eating human feces, what is there which could possibly anger you?

I mean, have you ever considered the parasites which commonly inhabit the human gut, not to mention the dangerous diseases, viruses, fungus, prions, etc?

And to think, before this, I was worried about GMO foods and getting
them labeled!

Now I am beginning to feel I am up "synthetic food" creek without a paddle!

Regards,
JS

What influence has a metallic boom on a Yagi antenna?
Normally the design is made without taking the boom into
consideration.

http://yfrog.com/janextgen14p

The voltage curves on the parasitic elements have their maximum
in the center. When using a non-conductive beam the situation is not
affected.

With a metallic boom and with the parasitic elements fastened
to the metal would the oscillation pattern be changed?

http://img28.imageshack.us/img28/3096/boommounted.jpg

Do I have to insulate the parasitic elements from the metallic boom
or is it advisable and allowed to fix them with metal fasteners?
Does the connection have to be made electrically good,
or does it not matter at all?

In fact there are both designs used, but probably without further
consideration. Some manufacturers use plastic holding clamps
for mounting the elements, for no other reason than saving time
during assembly. Other manufacturers just drive a self cutting
thread screw through everything.

The YAGICAD software does talk about mounting elements
on the boom, and NEC is too difficult for me to understand.

Thank you in advance for your answers, and a sixpack
will be kept ready to compensate your efforts at your next visit.

w.

No necessarily, but it is common to design for a non-conductive boom and then make

a correction to element lengths for the type of boom in use.
>

That is not true.

> With a metallic boom and with the parasitic elements fastened
> to the metal would the oscillation pattern be changed?

Depending on how the boom is or is not bonded to the element, and the geometry (sizes, position etc), the conductive boom may reduce the magnetic flux nearest to the element, effectively reducing its inductance in the middle area, so tuning it higher.

> Do I have to insulate the parasitic elements from the metallic boom

If the 'connection' has infinite R (ie no connection) or zero R, there is no power converted to heat, otherwise you invite conversion of RF energy to heat.
>
>

Not by competent designers, they consider the effects of the boom.

Hello Helmut,

There is influence, whether or not the elements are electrically connected. When (thickness of the boom) << (element length), the influence is negligible.

When the above isn't met, you may experience a noticeable shift in design frequency (it will go up). when connecting the elements to the boom, the influence will be more. So to compensate for this, the elements should be somewhat longer. Note that it also depends on where the metallic contacts are. An element through a boom will experience more shift then an element having just a single-point electrical connection to a boom.

When you have bad connections (for example due to corrosion or a loose nut), movement (induced by wind) will change the electrical characteristics in a time varying way. This may result in cracking noise, even on strong signals. Clean strong signals may introduce noise at other frequencies due to the time varying change in antenna properties.

This may be a reason for manufactures to use non-contact mounting of beam elements. I saw several UHF yagis (with relative thick square booms w.r.t. element length) with loose elements making (bad or no) contact with the square boom. So if you decide to make electrical contact, make sure it is long lasting.

Here you may find useful info http://www.qsl.net/yu1aw/Misc/vhf_ant.htm

With kind regards,

Wim

Thanks, and also thanks to Owen,

I made an error in the description
http://yfrog.com/janextgen14p
because those are current curves, not voltage.

What I learned is, a metallic boom requires a small +length correction
of the dipole elements. YAGICAD does it automatically with a cryptic
value called L+BCF (boom correction factor?)
An electrical connection with the metallic boom will need more
correction than an isolated element mount, if I am correct.

A metallic boom should also affect dipole spacing,
but to what extent, I do not know.
YAGICAD does not care for that, or does it?

Am not sure.

w.

Yes, that is correct. I failed to equate the 60 deg angle of the reflection coefficient at the point of observation, which is ~.167 wavelengths (30 deg) from the load. Thanks for keeping me straight.
Sincerely, and 73s from N4GGO.

If you Google for "boom correction factor", you should find a wealth of discussion on the subject. It is not all cut and dried, it remains an area of active research.

An interesting experiment might be to cast the upper elements above a
metal slab of 1/4 wave depth which extends a full wave out in all
direction of the compass, in eznec/nec/mmana, and serves the purpose of
the lower elements connected to a huge boom.

A comparison between a standard yagi and such a design should show a
stark comparison of the importance/function of the lower/ground
elements, between the two. Or, perhaps just the extension of the boom
in the frontal and trailing directions would provide usable data.

In any case, I suspect the influence of the boom, in such a greatly
exaggerated example, would be exposed in more defining light ...

What could be done to the upper elements, reflector(s) and director(s),
to provide such a comparison(s) is a matter which provokes thought ...

Frankly, I don't even know if any antenna modeling software would allow
such an "abuse."

Regards,

JS

Yep. It does sound like a public relations article.

>I guess I am the lightweight here, just the thought and reading that
>article made me gag ... I thought it would provoke more anger in
>Americans ... I mean, if you don't get angry about people eating human

>feces, what is there which could possibly anger you?

You might want to travel a little. Most of the links to exotic foods that I posted were from foreign countries. What we consider inedible is common elsewhere. For example, in the west, we don't eat bugs (insects). Yet, the rest of the planet has no problems with bugs. With our present path toward inevitable doom, it's likely that some manner of famine might become reality. It's then that we'll need to expand our list of acceptable foods, or starve. If you've ever survived a survival class, you'll understand the problem.

>I mean, have you ever considered the parasites which commonly inhabit
>the human gut, not to mention the dangerous diseases, viruses, fungus,
>prions, etc?

Sure, and that's the problem. With farm animals, it's a fair assumption that the animals feces came from a fairly healthy animal. With human waste, it's not such a great assumption. The extra junk found in human feces are not easily processed. (Drugs, Bugs, and Slugs; also known as medicine, bacteria, and parsites). While it can be cleaned up with a mix of chemical and alpha-particle sterilization, that makes it too expensive to be useful. I suspect that's where the high cost of processing mentioned in the article originated.

>And to think, before this, I was worried about GMO foods and getting
>them labeled!

Known problems are not worth worrying about. It's problems that are currently unknown or un-discovered, that are the real problem. That's the real problem with GMO. We don't know what eating them will do, therefore, we assume that it will be bad, and should avoid it.

>Now I am beginning to feel I am up "synthetic food" creek without a paddle!

We haven't even started talking about mining hydrocarbon compounds, and cracking them into edible substances. Coal tar derivatives are just the beginning. You could easily eat coal, with the appropriate flavor and texture additives.
<http://pubs.acs.org/doi/abs/10.1021/ba-1966-0057.ch020>

Eat anything with with red dye? It's probably made by boiling Cochineal bugs. That makes it a "natural" dye:

Yes.. not a lot, but important on a high gain antenna (one that is "super directive".. i.e. has gain > N, where N is number of elements) because the amplitude may not change much, but the phase might, and small phase errors ruin the nulls in the pattern, which degrades the overall directivity.

A modeling program like NEC can easily show the difference.

>
> http://img28.imageshack.us/img28/3096/boommounted.jpg
>
>

That's the distribution of the voltage, but your picture doesn't show phase and magnitude, which is what's important.

There are a whole variety of techniques to account for the boom in a model, ranging from actually modeling the boom (tricky with some modeling codes) to empirically determined correction factors.

>
> Do I have to insulate the parasitic elements from the metallic boom

It does matter. What you really don't want is something that changes. Either always connected or always insulated is what you want.

>
>

> The YAGICAD software does talk about mounting elements
> on the boom, and NEC is too difficult for me to understand.

basically, a directive antenna gets its directivity from having different phase and magnitude of current in each of the elements. In a Yagi-Uda, only one element is driven, so the current in the other elements comes from mutual coupling among the elements.

That coupling is affected by the spacing, length, and diameter(s) of the elements, so having the boom connected is sort of like having an element that is somewhat "fat" in the middle. It's slightly different.

On a 3 element wideband Yagi, the "boom correction" is going to be pretty small. But on a 432 MHz moonbounce array with 20 elements, and where you want very low side/back lobes to keep the noise temperature down, it gets more important.

back before computers got fast and cheap, there were a lot of analytical (or semi-analytical) approaches to designing Yagi antennas. You'd have an approximation of mutual coupling (from, say, King) and form a matrix equation. You'd figure out what element currents you wanted for your pattern, and iterate your element lengths and spacings until it all worked out. (or, you use the matrix equation to determine the element currents, given the excitation, and then calculate the pattern from that, using simple phased array techniques).

The problem is that simple approximations like King's typically assume constant diameter elements. So, by dint of a bunch of empirical work, people found "correction factors" that you could apply to an idealized model (no boom) that would make it work ok on a boom.

> If you Google for "boom correction factor", you should find a wealth of discussion on the subject. It is not all cut and dried, it remains an area of active research.
>
> Owen

basically, it's all about coming up with a simple algorithm to allow the use of a simpler modeling code (i.e. model without boom, apply BCF, done).

It all depends on what is "good enough". On an HF beam, the elements typically sag a fair amount, and wave around in the wind. Furthermore, the boom is a tiny fraction of the element length so it has a "small" effect (e.g. 10cm boom on a 10m long element) . So the uncertainties in performance due to other mechanical factors are bigger than the effect of a boom.

On a 432 or 1296 yagi using a 2cm square tube as the boom, though, this is less the case. The elements are rigid, 2cm is a big fraction of a 35 cm long element. And, on VHF/UHF, one typically has a LOT more elements and a LOT more gain, so the tolerances on everything are much tighter to get the desired performance. If one were build a 5 wavelength long 20m Yagi (5 lambda isn't unusual for 2m or 70cm), you'd be worrying about those sorts of effects too, at least if you wanted to get the 17dBi gain that might be possible.

On any scale which would compare the eating habits of a stone age race
to those eating habits today, it would not even register to the eating
of ones own feces, or ones own species feces, that is a real DUH! moment ...

However, your comment makes me consider that some will more willingly
come to consuming their own feces, than others ...

I mean, there is little problem with killing a chit eating dog, unless
that dog is ones own ... might serve as a proper mental model.

Regards,
JS

;-)  Well, I'm not sure if you also sent that to my email address; I
didn't see it there.  And of course, I didn't see it here, since I
never "sort by date" -- at least not till now, when I've managed to
find a free newsgroup server where I can see the messages.

I'm happy to see that Owen has jumped into the thread with his usual
well thought out postings.  Measuring S-parameters (which includes
reflection coefficients) and using them in calculations has been the
topic of a great many articles.  There are some good Hewlett-Packard
notes on them that I believe you can get from the Agilent website, and
if not there, from other archives.  HP AN95-1 and HP/Agilent AN154 are
a couple, but Googling "S Parameter Application Note" will get you
lots more.  Honestly, I'd have to say they are a better place to try
to learn this sort of thing than threads here...

Cheers,
Tom

Available at:

http://www.sss-mag.com/pdf/an-95-1.pdf

One interesting thing about the s-parameter equations is that if one squares them, one obtains the irradiance (power density) equation from the field of optics. For instance:

b1 =3D s11*a1 + s12*a2

are the normalized voltages where b1^2 is the reflected power toward the source. Squaring the right side of the equation uncovers the interference term, 2*s11*a1*s12*a2. If that term is positive, the interference is constructive. If that term is negative, the interference is destructive. Zero reflected power toward the source indicates total destructive interference toward the source and that is the goal of tuning a system to zero reflected power incident upon the

```
source.

IN general, the boom extending front or back doesn't make a big

difference. If I had to "rule of thumb" it, I'd say that the
"influence" of the boom is several element radii.

Step right up and fire up that copy of HFSS or ADS

in most modern codes you can model *anything* given sufficient time to build the model and run it. If you have lots of big chunks of "stuff" a method of moments code like NEC might not be the best choice. One of the FDTD or similar codes might be better.

A slab of aluminum 1/4 wave deep and extending a full wavelength is all
directions is about as perfect a conductor/elevated-pseudo-ground as I
could ever imagine ... yep, you pictured it correctly ...

Certainly for the front director, and back reflector, it would look as
two legs of the ground plane from a vertical ground plane antenna --
with the bottom dipole element still attached ...

Having all the antenna I want, at this time, I am just too lazy to load up mmana and see the results ... most run-of-the-mill and been-around-forever antennas have pretty much been optimized for cost of materials/work to benefit ratio ... I don't think I have seen anything new, or even claimed to be new, in decades ... or longer!

Regards,
JS

Let's return to an earlier example and compare a single-port analysis with a dual-port analysis.

```
100w
source--50 ohm--+--1/2WL 291.4 ohm--50 ohm load
```

The 50 ohm Z0-match point is at '+'. The forward power on the 50 ohm line is 100 watts and the reflected power on the 50 ohm line is zero watts. The forward power on the 291.4 ohm line is 200 watts and the reflected power on the 291.4 ohm line is 100 watts. 100 watts is being sourced and delivered to the 50 ohm load.

The voltage reflection coefficient, rho, at the load is (50-291.4)/(50+291.4)=0.7071. The power reflection coefficient, rho^2, at the load is 0.5, i.e. half of the power incident upon the load (200w) is reflected (100w). Since the load is a single-port, these parameters are consistent with a single-port analysis. In a single-port analysis, we cannot tell the difference between a virtual reflection coefficient and a physical reflection coefficient.

The problem comes when we use a single-port analysis on the Z0-match point. Since the reflected power on the 50 ohm line is zero, a single-port analysis would yield rho=0.0 and rho^2=0.0 when viewing the Z0-match from the source side. When we perform a dual-port analysis, we get different values for rho and rho^2, i.e. we get the complement of the reflection coefficients at the load which is a characteristic of any simple Z0-match similar to the above example.

For a dual-port analysis, rho looking into the Z0-match from the source side is (291.4-50)/(291.4+50)=0.7071 and rho^2 looking into the Z0-match from the source side is 0.5, the same as at the load. Looking back into the Z0-match from the load side, the sign of rho is negative just as it is at the load with rho^2=0.5, the same as at the load.

Since the two analyses yield different values for the reflection coefficients, which analysis is correct? The answer gives the clue to the resolution of this discussion.

I think you're generally right. What the tools give you is the ability to make a "semi-custom" design that's optimized for a purpose slightly different than everyone else.

For instance, you might want a 20m Yagi that's optimized for 14.300 as opposed to 14.050 or something.

Various and sundry multiband schemes also come to mind. Lots of alternatives for element layout, lots of potential interactions. And these designs are not well accommodated by analytical techniques or cut and try on the physical article (because of the interactions at frequencies well away from the resonant frequencies of some elements). Doing something like a Force-12 C3 tribander by cut and try would be tedious at best.

In the VHF/UHF world, where very high directivity is the rule, and people worry a lot about side/back lobes (for antenna noise temperature reasons), and because the structure is significant in size compared to the elements, I think modeling codes are almost essential. And, there's lots of alternatives to look at (element through the boom, on top of the boom, connected or not, spacer or not, etc.)

One thing I always like doing is shopping for pet food with the wife,
and especially reading the labels ...

"Animal Digest" is a nice term on some of the cans and packages, and
basically translates into, "Stomach, intestines and anus -- AND THEIR
CONTENTS, all are included for your pets personal enjoyment!"

I just quietly put back the container, and quickly look around to see if
anyone has seen me touch it ...

Regards,
JS

ok, i'm afraid i'm going to have to ask the simple question... if you
blackbox the load and stub and look at just the one connection to it
and that gives you no reflected power... where do you define the
second port, and why?

Logic, immediately, suggests to me, that varying the frequency and
measuring voltage, amperage, and SWR would begin to immediately point
the answer(s.)

A 50 ohm, non-reactive/carbon load would complicate matters, so naturally, I am assuming that is NOT the case ...

Regards,
JS

The current is maximum at the center, not the voltage.

>

At HF the effect is normally minimal depending on the mounting method used. Using insulated through the boom mounting it starts to be noticeable at 2m and by 70cm it definitely needs to be compensated for.
  1 and 1/4 inch booms using Delrin through the boom mounts at 432 need about 7mm added.

The previous statements assume you don't use insanely large booms and mounting pieces.

Dead right.

This seems to be one reason why yagis at HF tend to be grounded elements
and at VHF and up tend to be insulated. At HF it's fairly easy to get a
low resistance with fairly low impedance change over a few years.
That's harder to do at VHF especially with through the boom uninsulated.
  Hence through-the-boom or over-the-boom insulated at 2m and up.

I've built many 6m beams with no correction added and using simple
homebrew U clamps. I have seen little discernible difference in their
performance from predicted. Of course I shouldn't except perhaps in the
side nulls. And they seemed about right. One small confirmation was
the SWR curve also matched predicted.

Anyway, the problem with connected is corrosion. Can only slow it down.

For the two-port analysis, only the impedance discontinuity at point 'x' is in the black box. One port is the source side of the impedance discontinuity. The second port is the load side of the impedance discontinuity. It allows the standard s-parameters to be measured and the standard s-parameter equations to be used.

On the source side of the impedance discontinuity:

b1 =3D s11(a1) + s12(a2)

On the load side of the impedance discontinuity:

b2 =3D s21(a1) + s22(a2)

Those are the normalized voltage equations. Squaring those equations shows what happens to the component powers including interference components. Reference:

IMO, the resistor load simplifies things as a single-port analysis can be used on a resistor because there is only one component of power accepted by the resistor. What would complicate things, IMO, is a 50 ohm antenna feedpoint impedance which is a virtual impedance. Analyzing the antenna as a multiple port device shows where the multiple energy components go which is a complication of the present point I am trying to make about the Z0-match point 'x'.

However, the single-port vs dual-port analysis differences at the impedance discontinuity 'x' also apply to the analysis at the load resistor vs an antenna AND at the source where Walt seems to be using a single-port analysis involving a virtual source impedance which depends for its very existence upon forward and reflected energy components flowing in opposite directions at the source impedance point which necessarily causes interference accompanied by a redistribution, not a reflection, of energy components.

I have a Heath HM-2102 VHF SWR power meter 50-160 MHz
0-25 and 0-250 watts. Excellent condition.

I'm *asking* $40 plus shipping.

It can be viewed at:

http://home.comcast.net/~hsknoll/site/?/photos/

Based on a fair number of simulations over the years, I'd say that SWR curves are not very sensitive to pattern degradation (except in an egregious case)..

Consider a 5 element medium gain Yagi where the currents are all roughly equal (which is what you'd have with moderate superdirectivity) and it has a F/B ratio of, say, 20dB.

Screw up the current in one of the elements by, say, 25% (so the overall excitation is now off by 5%).. That's enough to turn your -20dB null into a -10dB null (in round numbers..)

But, would you even see that in a VSWR.. say it was 1.2:1 before (reflection coefficient = 0.09).. and now the reflection coefficient changes by 5%.. so it's 0.0945.. That's a VSWR of 1.208.. I think you'd have a hard time measuring that..

I thought you might enjoy that Cecil ... I know you were really worried that RF would be failing us soon, due to a lack of suitable media ... ROFLOL!

I am sure you noticed these "jewels in the article:"

"The limit means that more virtual photons exist outside the mirrors than between them, creating a force that pushes the plates together. This 'Casimir force' is strong enough at short distances for scientists to physically measure it." -- From the article, itself.

"David - Dr. Wilson's article (ref. 1 for the article) is the source of my statement that linear acceleration cannot produce "this effect". It seems that "this effect" is the dynamical Casimir effect. The Unruh effect is something different (but definitely related). In any case, I thank you for your clarification." -- From a post, further down.

Things are happening ... finally the squeeky wheel gets some much needed maintenance ...

But cecil, with a 50 ohm NON-inductive load (not inductive over all
freqs of concern), fed by 50 ohm line, from a 50 ohm source ... would
find a stub a bit of a problem ... indeed, a shorted stub more so --
choice of proper line length and placement of the stub would allow its'
use, on very limited frequencies, with excellent dummy load results, but
the need, ever, escapes me!

Anyway, I just commented to piss old dave off ... :-) I admit it!

Regards,

but what is your second source? you can always represent the second
source in that case in terms of the transmitter output so the second
input can be eliminated giving you a single port model.

On 6/23/2011 4:11 PM, Mike Coslo wrote:

[nothing, really ...]

Seems even Einstein removed it from the realm of "ponderable media", and
you have known all along, what it is ... enlighten the rest of us, and
we can see the revelation you have had!
```

And, let me see, ether vs. quantum sized particles? Any relationship? NAAAA! ROFLOL!

It is like Einstein was never understood in the first place. It is like this is the first time these people have been exposed to what he said, like they will need time to digest all this ... simply amazing ... correct me if I am mistaken, but the ether defines our very matter and describes the laws which that matter must obey, right? The ether is the rod and measure, right? If a universal clock and time frame exists, it exists only within the ether, right?

If you don't say yes to all the above, I can only think you a kook, or unable to understand what has been written and, generally, accepted ... of course, it is being questioned, as it should be ...

"He went on to add �We�re in a very special moment of history, because we are like fish who finally realized we were living in water."
http://thedartmouth.com/2010/05/07/news/space

All I know is the ether is a media, it is invisible to us, its' properties can only be "deduced" (or, guessed at), or seen though its' action/effects on "our matter. Yet, you can now tell me that the ether is NOT the subject of that article ... I'd say you either:

1) Have knowledge no other man has.

2) Have iron balls the size of bowling balls.

3) Are a moron.

I am pretty close to making up my mind ... ROFLOL!

If the ether is ever denied, it will be because some idiot, such as yourself, will step up and say, once it is fully "discovered", "THAT ISN'T IT! BECAUSE OF _BLANK_ ." And, attempt to ignore that Einstein, and very PURPOSEFULLY, left a place marker for the gravitational ether, in removing it from the realm of ponderable matter ... so, whatever IS the media which carries light and RF, whatever the media is which establishes the speed limit on light, whatever media is the UTF (universal time frame), whatever media composes "spacetime", "quantum foam", that IS the ether ...

What the hell are you looking for, easter eggs? Or, just some half-baked ego-centered way to deny ether? Really, I can't even see the purpose, just the insanity!

>I just remembered most of those external baluns are 1:1 baluns. I do have one external commercial 4:1 balun, and one 4:1 balun I hand wound from a schematic in one of my antenna books.

Hi Michael,

The odds are that the BalUns you wound are similar to the ones in your tuner(s) - and they will NOT do the job properly.

By properly, the BalUn MUST choke the line. This comes for free with the W2DU style, as there is only one way to build one, the right way.

The distinction is between what are called voltage BalUns and current BalUns. Frequently, web sites that purport to know the difference DON'T know the difference. The W2DU BalUn is an example of a current BalUn with a 1:1 ratio. It is also a choke. Very few BalUns that are published on the web are current BalUns. Similarly, very few have the necessary choking action.

One solution is to feed a W2DU BalUn, that in turn feeds any BalUn with the required transformation ratio, that then in turn feeds the antenna. The W2DU BalUn takes care of the proper choking action needed. However, this may not work with the internal BalUns found in nearly every tuner on the market. (How does one insert the choke to an internal BalUn?) Problem here is that if there is ANY path to ground that goes around the choke, you have just made it an exercise in futility.

And lastly, you have described a number of problems with the antenna that were both inside and outside of the focus of gain. ALL were functions of Common Mode currents. Choking the line is the best all-around solution.

Okay. I take that back. I just ran a simulation with EZNEC and it shows
twice as much uV available at the receiver than Radio Mobile, so my
conclusion is that a pattern null is not involved. I'm stumped.

73,
John

I have a wearable camera and transmitter in my underwear. Does that
make me a weirdo?

Many systems that include a need for portability with something approaching continuous coverage need to use diversity reception to achieve this. The problem of nulls at these frequencies is quite bad, as we all know when we try to use mobile phones..It only works if I stand on a chair and raise my right leg, syndrome.

Brian

Or do what I do. Mount it on a tripod and aim it so you can shove two legs again the rail and hold it place with a bungee chord. That makes it a breeze to take in and put up.

You could make a sort of customized fixture, too, that "mates" with the railing, so that you just sort of click it into position, and it's automatically aligned properly. A piece of wood with notches that align with the vertical rails, for instance. If you want something more weatherproof than wood, a polyethylene cutting board makes a great material to work with. Easy to cut, indestructible, etc.

Velcro is also your friend. A strap with velcro to snug it up against the rail would work pretty well. Much faster than some sort of clamp scheme, typically, and less likely to arouse the ire of a landlord who doesn't want clamp marks. (any sort of screw clamp is inevitably going to loosen, or be over tightened, etc.)

Mount it atop a refrigerator unit, on the porch, use the refrige to keep
your beer in -- no one could ask you to remove that from the porch!

Update on the 10 meter Lazy H...

I did a little reading on ladder line at the web page below;

http://www.athensarc.org/ladder.asp

and then in the ARRL handbook.

With the knowledge gained form the two sources I made the following changes;

I changed the length of the 450 ohm ladder line feeding the antenna to make sure it was not a multiple of a 1/2 wavelength at 10 meters, and the antenna tuner was able to tune the Lazy H more easily. I also suspect there may be a problem with the balun in the Dentron MT-3000a tuner. When I hook up the Drake MN-75 tuner with the internal 4:1 balun I hand wound myself I am seeing gain from the Lazy H antenna in it's preferred direction compared to the dipole, but when I switch to the Dentron MT-3000a I am not seeing gain when I compare the dipole to the Lazy H. I think I am going to remove the factory balun from the Dentron MT-3000a and hand wind a new 4:1 balun for it.

Changes followed by "|".

The rec.radio.info newsgroup, first established in 1993, has been recently revived by an active moderation team. We are currently seeking suitable information, FAQ, and bulletin articles from the entire rec.radio.* newsgroup hierarchy for simultaneous cross-posting to our newsgroup.

We are seeking a replacement maintainer for the following information bulletin formerly posted to rec.radio.amateur.* (and currently archived at http://www.faqs.org/faqs/radio/personal-intro/):

radio/personal-intro
Subject: Guide to the rec.radio Newsgroups
Maintainer: jeffreyh@Hawaii.Edu (Jeffrey Herman)
Last Posted: 9 Nov 2001 06:18:17 GMT
Posting-Frequency: 15th of each month

One significant omission, requiring immediate updates, for this article |
is that it does not mention newer amateur radio newsgroups created since |
it was written, including: |

rec.radio.amateur.antenna |
rec.radio.amateur.boatanchors |
rec.radio.amateur.dx |
rec.radio.amateur.equipment |
rec.radio.amateur.homebrew |
rec.radio.amateur.moderated |
rec.radio.amateur.space |

We are willing to provide any technical support necessary to get this article updated and automatically posted again at a regular interval. This would include establishing contact with the original maintainer for any necessary permissions. We would prefer to seek a new, dedicated maintainer at this time, rather than start auto-posting the original article ourselves.

For more information about our newsgroup, see:

http://www.panix.com/~rram/usenet/rri/index.html

Please direct any comments, questions, or criticisms to rec-radio-info-request@panix.com.

I did some searching on the Internet concerning the use of the Dentron
MT-3000a tuner and using the balun for 450 ohm ladder line on10
meters, and I found the following post from K8JS on a eham.net review
of the Dentron MT-3000a tuner..

Below is K8JS's post on eham.net...

=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=
=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D
```

K8JS   Rating: 3/5   Feb 22, 2004 00:59   Send this review to a friend
Basically Is OK, but not the best Tuner Out There   Time owned: more
than 12 months

...<snip>...

I also ran balanced feedline antennas at that time, and discovered
that the built-in balun was badly UN-balanced at it's "balanced" port
for 10 thru 20 meters.
To help remedy that problem I had to replace it with a physically
larger, and much superior "Super Balun" from Palomar that barely
physically fit within the tuner's chassis.
So - with correcting the coil's grounded end making a better contact
to the chassis, replacing the unit's inferior balun, and gingerly
operating those flakey rectangular switched, I was able to continue to
use that otherwise very nice tuner for several more years. ---John,
K8JS

=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=3D=
=3D=3D=3D=3D=3D=3D=3D=3D=3D

Well, looks like it is time to replace the stock Dentron MT-3000a 4:1
balun with a home made one.

Bad idea. It might work in transmit, but in receive, all you're going to hear is the broadband noise coming from whatever data is moving on the ethernet pairs. There is some isolation between the CAT5 wire pairs, but not enough to prevent noise coupling entirely. Even if you borrowed and isolated one of the two pairs used for 802.3af and 802.3at for the antenna, you would still experience considerable noise pickup.

"When all the bad ideas have been eliminated, whatever remains, no matter how improbable, must be a good idea."
(Me, in about 1980 during a design review)

>Is it a silly and dangerous idea?

If you mean using the power line for part of an antenna, and the earth ground (through the power lines) as the rest, it's both dangerous and impractical. One mistake in wiring an you have a fried customer. The impedance of this contrivance is also indeterminant and non-constant, making matching both a transmitter and receiver difficult and expensive. The low impedance of the ground loop (almost a short circuit) is going to be difficult to match at both 1MHz and 100Mhz. There's also an amazing amount of RF noise present on the power lines, which your AM/FM receiver is not going to appreciate.

In the distant past, I recall some vendor adding a 4th wire to the power cord, and using it for an antenna. It worked when there was fairly clean power, but failed badly if there was a noise generator (usually motors) on the line.

Back in the early 1960's, I got my childhood start in electronics when I read an advertisement in Popular Electronics(?) for a power line adapter to "Turn Your House Wiring into a Giant 1000ft TV Antenna". Inside the magic box was a "capacitator", which coupled the twinlead antenna terminals to the AC power line. It didn't work, but I didn't know that. This was in the days of AC/DC radios and TV's, with no AC transformer isolation. I was saved from a premature demise by reversing the power plug to see if it would improve reception, and blowing the main fuse.

Not so dangerous or silly, in all reality.....

Apparently you have never heard of "Carrier Current Transmissions".... Back 4+ decades ago, I was Chief Engineer of a College Campus Student run Radio Station, that used the Campus Power Distribution System as the Transmission Line and Antenna for our AM Broadcast operations. Each of the Systems transformers in each building was bridged with .1 uf 10,000 Vac Capacitors to conduct the RF around them and into the buildings. All the Distribution was done via buried Metal Conduits, which acted like coax, and kept our "Over the Air" Signal Strength within FCC Part 15 Limits at the time. We used a 100 Watt Transmitter coupled into the Secondary of the Main Campus Feed SubStation Transformer, which was in an Basement Vault, in one of the Campus buildings. Worked just "Spiffy" and we were even inspected by the FCC yearly and were in compliance with all FCC Rules and Regulations for Part 15 emissions, in place at the time. Same basic concept is still used today, by the X10 System of Whole House Control Systems, and by the Ethernet over PowerLine Adapters that are in use today. Not Magic, just plain OLD Technology at work.

Touche. I helped build the initial FM station and later the AM carrier current system while a student at Cal Poly Pomona in the early 1960's.

The key component was a ferrite transformer, that would pass 1MHz RF, but not 60 Hz AC. I forgot the name of the vendor. There was one central transmitter, a power splitter, coax cable to each of the dormitory buildings (because each had separate power xformers), and a ferrite transformer RF coupler to the building power lines. It worked, but student that were accustomed to the FM (mono) quality were disappointed with the noisy AM signal. I vaguely recall that it lasted about 5 years after I left.

Other than running underground cables, dealing with building inspectors, and handling listener complaints, I didn't have much experience with the carrier current AM hardware. It worked, for AM.

However, the author also wanted FM, presumably for an AM/FM receiver. Transmitting carrier current AM is one things, receiving is another. For entertainment value, put a small value capacitor between the antenna terminal of your receiver or spectrum analyzer and the power line. Yes, it will be mismatched and lossy, but good enough to demonstrate the large amount of noise found on the power lines.

Carrier current ethernet (HomePlug) does a decent job of moving data through such noisy lines by using broadband techniques 2-28Mhz for HomePlug AV, 2-50Mhz for IEEE901, and more for HomePlug AV2. With such lavish bandwidth, communications frequencies can be dynamically adjusted to use only those frequencies that aren't being clobbered by noise and interference. That can't be done with broadcast AM/FM, where each station is stuck on a specific frequency.

The only people that claim that X10 works are those that haven't used it. I have quite a collection of X10 and BSR modules sitting in a box somewhere. The problem is that X10 is a one way protocol. You send, and hope that something happens at the other end. No handshake, no error recovery, no reliability. I've used it in various locations with disgusting results. X10 also doesn't communicate audio, but various "wireless" intercoms that use the same 120Khz carrier frequency. I also have a few of those stored, after I became tired of the line noises and buzz it would belch.

You do have a point, that is possible to use the power lines as an antenna or communications media safely. However, judging by the quality of the original question, I suspect that the OP might not be very well versed in how to do it safely.

I'll buy whatever you have.

I've been using it for 20 years or so, maybe more, not sure. Doesn't miss a beat. It depends on how you use it. Don't try to control things on other phases/other side of 220.

Similar to the issues with building BPL where you need to feed all phases. BTDT too. And in-building BPL, at least as built by Motorola in the mid 2000's, doesn't make much more than S9 even if the coax feed is connected directly to an amateur receiver, so is ham friendly. It may no longer be so, no data available after 2006 for me.

Sure. I'll collect what I can find and send you a photo. We can
haggle later over the price (i.e. anything that covers the shipping).

>I've been using it for 20 years or so, maybe more, not sure. Doesn't

There are tuned xformers to couple the 120Khz to different phases.
<http://www.smarthome.com/4820X/X10-XPCR-X10-Signal-Coupler-Repeater/p.aspx>
(You might find some of the user comments under the above URL rather
enlightening).

Sometimes, there's enough coupling between phases for it to work
without the xformer or repeater. Unfortunately, the places where I
tried to use X10 boxes were plagued with noisy power lines. Some of
it was the fault of the power company, which was eventually fixed
years later. The rest were HVAC motors, an electrostatic dust
precipitator, and oddities such as a negative ion generator, electric
shavers, and a noisy neon sign. I made the X10 work by programming
the controller to repeat all on/off commands 4 times, but that didn't
work with dimming or toggled outputs. After having someone slip and
fall in the dark, because the X10 system failed to turn on the outside
lights, the system was pulled and replaced with one that was hard
wired.

That would be the MU (Multi-Unit) system.
<http://www.netlinkweb.com/solutions/motorola/BPL-applications/BPL-MU.asp>
I have no experience with that one. Did you look at it on a spectrum analyzer? Motorola is one of the few BPL vendors that supplies devices that intentionally filter out "sensitive" bands, such as ham radio. My understanding (possibly wrong) is that since the entire building shares the same wiring, the bandwidth per user is limited during peak times.

User manual (9MB PDF):
<http://motorola.wirelessbroadbandsupport.com/software/sw_downlink_public.php?id=80806d75ff44060653d82a6204a05462>
See Pg 43 for the Bandwidth Manager settings. 42.5Mbits/sec maximum for the entire building.

Pg 54 has something called Power Spectral Density, which include mention that the power output is +22dBm (160mw) per carrier(?) for US rules, but can be cranked up considerably higher. With 84 channels, that's quite a bit of RF. Are you sure it's not a noise generator?

Pg 55 has the frequency chart, including notchos.
4.5-21Mhz, with notches at 5.5, 7.3, 10.3, 14.2-14.6, and 18.2Mhz. If you tested at 40 and 20 meters, you probably wouldn't have heard anything. Oddly, the notch at 18.2 should have been 18.1 for the 17 meter ham band.

Pg 78 shows how the user can monitor and set the frequencies in use.
It includes the comment:
"Grayed out values are reserved HAM radio frequencies and cannot be adjusted."
which may explain why you didn't hear much.

There are some interesting graphs starting on Pg 110.

Woohoo! The center fed Lazy H is now working with gain in it's most favored directions, and it is now consistently out performing the dipole. I had already pointed the extended double zepp in another direction, so I'm not sure if the Lazy H is out performing the extended double zepp.

Below are the following real world lessons I learned from building the Lazy H wire antenna in the real world. Hopefully it will save future builders some time.

1) Make sure the 450 ohm ladder line exiting the center of the Lazy H back to the antenna tuner goes away from the Lazy H at a 90 degree angle for at least a full wavelength or more or it will skew the radiation pattern of the antenna.

2) Cut the 450 ohm ladder line going back to the tuner to a length that is NOT a multiple of a half wavelength on the frequency (or frequencies) you plan to use the antenna on. In my case since I only plan to use the Lazy H on 10 meters I found the length required to get

back to the radio room, and then I added length until the total length landed in between multiples of a 1/2 wave at the antenna design frequency. The antenna tuner was more easily able to tune the Lazy H once I did that. When I measured the total length of the ladder line feeding the Lazy H I included one half of the phasing line that connected the top and bottom elements.

3) Do not allow sag in the ladder line back to the antenna tuner where the exiting ladder line falls close to the bottom half of the 450 ohm phasing line that is used to connect the top and bottom of the Lazy H or the SWR reading will go up noticeably.

4) The setting on the antenna tuner where a lowest SWR is tuned may not be the same setting where the receiver receives the strongest signal from the antenna. This quirk may be specific to my Dentron MT-3000a tuner and it's internal factory balun.

5) Following number 2 above will probably avoid this situation, but if your antenna tuner is unable to match the Lazy H at any setting change the length of the ladder line feeding the Lazy H.

Dear Michael KS4HY: Thanks for the up-date. You have indicated some ways to deal with the issues you encountered.

To emphasize what others have said: The issues you encountered would have been attenuated with common-mode chokes being used at feed-points (and perhaps at strategic places farther along).

 I've noticed several sites (and books) show screen reflectors for
various multiple driven element broadside arrays, but I have not seen
any dimensions given for a screen reflector.  I am aware that a
parasitic reflector for a yagi is about 5% longer than the driven
element.  Is the same true for a screen reflector for a broadside
array like the Lazy H antenna?

For instance, since the total length for the two top horizontal 1/2
wave elements in a Lazy H are generally 1 wavelength long plus the
width of the center insulator does that mean a screen reflector should
be roughly 5% longer than the total side to side width of the Lazy H
antenna? Also is the best spacing between the Lazy H and the screen
reflector the typical 0.2 wavelength shown for a Yagi beam antenna
driven element and the parasitic reflector? If not is there a formula
for determining the width and height of the screen reflector as well
as the spacing between the Lazy H and the screen reflector for a
broadside array like a Lazy H?

Thanks,

Michael Rawls

Screen reflectors aren't critical in terms of size.. bigger is better, of course, and there's some sort of point of diminishing returns, but basically, it's providing some approximation of a "infinite perfectly conducting plane"... Sort of like a counterpoise for a vertical monopole..

Now, one could greatly reduce the amount of wire needed at the expense of bandwidth, etc., by putting a tuned reflector in, as you've noted.

In what universe does a hard shutdown cause a head crash?

The reason you don't want a hard shutdown (other than spyware having to flush everything it has gathered out the network interface) is to make sure everything gets written to disk.

Painful to lose the last few seconds worth of disk updates, perhaps, but far from a head crash.

And, yes, remote management consoles are useful.

You should always use the tuner setting that provides
an acceptable match using the least amount of inductance.
"coil turns, or wound inductor tap setting".
I think you will find that the settings that provide the
least loss, and yes, the receive noise is one way to gauge,
will correspond with the settings using the least inductance.
And the match doesn't have to be a perfect 1:1.. As long as
the rig will put out full power, it's good enough.

I looked at it band by band for the US amateur bands. I believe I also check out of band here and there, but it was 5 or 6 years ago. And that was straight from the transmitter level with a 1 meter cable and a 75 to 50 ohm mismatch.

I also swept our area 30 to 30 on HF with a not great hunk of wire and heard nothing beyond the normal ethernet, PC, printer and other office furniture. But nothing from the BPL which had a noticeable pattern.

Shared bandwidth is an issue, but it is also split up by phase, and that helps somewhat.

Hello, I have some doubts about standing waves on antennas that I hope
you could clarify!
As far as I understood, in a generic transmission line where we want
only carry power from a source to a load, we need to cancel the
reflected wave by adapting the load with the impedance of the line.
The result of this operation is S11=3DS22=3D0 and VWWR=3D1 that means no
```

standing waves.
As far as I understood, in an antenna we want to also avoid standing waves by having VWWR=3D1 in order to avoid overloading problem to the power stage...
From theory I know that the best radiating condition for an antenna is when it resonates, that is, when there is a standing wave=85 is that correct? How this condition is compatible with a VWWR=3D1 (no standing waves) for a good antenna matching? Is there something that I=92m not catching?

Regards,

Camelot

I don't know that I'd say that "the best radiating condition for an antenna is when it resonates," necessarily. But certainly a resonant antenna is one that will have standing waves on it when it's excited.

However, the standing waves on a resonant antenna result in radiation by the antenna, and the result of the standing waves, the radiation, and the resonance is that the feedpoint of the antenna looks like a resistance that absorbs power. The exact resistance depends on many things, but in general it's a resistance that either directly provides a good match to a transmission line, or else can be matched to a transmission line with a few components.

By the way, it's also not necessary to have the antenna matched to the transmission line: although a particular line with standing waves delivering a certain amount of power to a load has more loss than the same line delivering power to a matched load (no standing waves), the additional loss from the standing waves may not be a big issue. In fact, it may be better from a lost-power standpoint to use a higher impedance open-wire line with relatively high standing waves, than to use a low impedance line (e.g., coax) with low standing waves, because the loss in the open-wire line can be very low. There are lots of other factors to consider, too, but the point is that you shouldn't assume that it's necessary to get the lowest possible SWR on the transmission line.

Let's take one more step back from this problem. The antenna, whether resonant or not, presents some impedance at its feedpoint. The purpose of the transmission line is to couple power between a transmitter and the antenna feedpoint (or from the antenna feedpoint to a receiver). You don't need to know what's actually going on in the antenna, you only need to know that feedpoint impedance, to select the proper transmission line and possibly a matching network between the line and the antenna's feedpoint. (Well...you also need to be aware of how the metallic conductors of the transmission line may upset the fields around the antenna and possibly provide for decoupling the feedline from the antenna's fields, but that's separate from the issue of coupling power between the antenna and the transmitter/receiver.)

Keep the details of how the antenna does its job--how the current is distributed on the antenna's conductors--separate from how you get power to and from the antenna, and you should be OK.

Cheers,
Tom

Hello Camelot,

Resonance in the antenna is not required for producing RF radiation. Horn shaped structures and flared transmission lines are good radiators over frequency ranges that can be over 1:5 (for example 1 GHz to 5 GHz). These wide band antennas rely on travelling waves in their conductors. When the wave goes from the feed point towards the end of the structure, it gradually attenuates because of the lost energy due to (desired) radiation. The distribution of the current in the antenna's conductors (amplitude and phase) determines the radiation pattern.

Antennas made from thin wires show inconvenient impedance, except for some special lengths. The best-known example is the halve wave center-fed dipole. It gives a good match to coaxial transmission lines. Though it has a good match to a 50 Ohm line (so no standing waves in the transmission line), there are standing waves in the antenna. The sinusoidal voltage and current distribution in a half wave dipole is because of the large VSWR inside the antenna itself.

So the halve wave dipole fed from a 50 Ohms line shows high SWR in the antenna, but low SWR in the feed line.

The full wave dipole is also in resonance (two end-fed halve wave antennas), but its impedance is in the several hundreds Ohms to kOhms range (depending in wire thickness). It has somewhat more directivity then the half wave dipole, but gives large mismatch to coaxial transmission lines. If you drive the full wave dipole directly from a coaxial line (and do the matching in the shack), you will very likely lose most of your transmitting power (in the form of heat in the coaxial feed line).

The full-wave dipole can be fed from an open wire transmission line (ladder line) directly. There will be mismatch at the antenna-feeder transition, but it will be less (ladder line has high char. Impedance). As Tim said, the loss (or attenuation) of the ladder line is significantly below that of coaxial transmission lines, so even high VSWR inside the transmission line will not lead to significant line loss.

Short antennas (length < 0.1 lambda) are good radiators, but their impedance can be so weird that it is impossible to match them to a convenient impedance without excessive loss. The losses are in the matching networks, not in the radiating structure itself.

So generally spoken, resonance (that is ohmic antenna behavior) is not required for an antenna to radiate.

Regarding transmission lines.
Zload =3D Zcable, is not required for long lines, but gives the lowest loss. Depending on your requirements, you may accept some mismatch between load and line (so standing waves in the line and somewhat increased line loss).   Ladder line (parallel wire transmission line) can be used with significant SWR inside the line with relative low loss. The same SWR in a coaxial transmission line with same length may result in too much loss.

Transmission sections are used in matching networks. Well-known example: quarter wave transformer. It does function because of a standing wave part inside the quarter wave line.

Regarding the PA.
The PA just wants to see a certain load impedance to operate properly. With "properly" I mean delivering the stated power without too much stress on the PA's components.

With kind regards,

Wim

Please forgive the unfinished posting above. It happened without any action on my part.

First of all, one needs to get one's nomenclature correct. Antennas like single-wire dipoles and full-wave loops are Standing Wave Antennas. Standing Wave Antennas always have standing waves on the antenna. They may or may not have standing waves on the transmission line.

The 50-75 ohm feedpoint impedance of a 1/2WL dipole is a virtual impedance, the result of forward and reflected waves superposing into standing waves on the Standing Wave Antenna. The SWR on the 1/2WL antenna wire is approximately 20:1. Only about 20% of the total energy in the RF waves on a 1/2WL dipole is radiated. If 100 watts is being delivered to the antenna and ~100 watts is being radiated, there is about 500 watts of joules/second stored on the antenna wire during steady-state.

Maximum power transfer to the antenna occurs when the antenna *system* is matched but it is not an impedance match. It is instead a *conjugate match*. A system with an SWR of 10:1 on the ladder-line may (or may not) be a near conjugate match. If it is a near conjugate match, maximum *available* power will be delivered to the antenna.

To summarize: Standing Wave Antennas, like 1/2WL single-wire dipoles, *require* standing waves on the antenna wire.

A flat system, e.g. 50 ohm coax to a 50 ohm antenna, is an impedance match but it is also a (trivial) conjugate match. In a low-loss system, a Z0-match guarantees a near conjugate match at the antenna feedpoint.

A low-loss system with tuned feeders is a (conjugately matched) system if the impedance looking one direction in the feedline is very close to the conjugate of the impedance looking in the other direction.

When a Z0-match to 50 ohms is achieved by a tuner (or other network) a near conjugate match is achieved in a low-loss system. In general, all low-loss systems that are transferring the maximum amount of available energy are matched, by definition, i.e. they are a near conjugate match.

The reason that I say "near" conjugate match is that the conjugate matching theorem doesn't allow resistive losses in the analysis. Of course, there is no such thing as a lossless system in reality.

Exactly. Standing waves are often our friend. When one feeds a 1/2WL
dipole with 1/2WL of ladder-line on 80m, one is depending upon the
standing waves to transform the impedance looking into the feedline to
the same value as it is at the antenna feedpoint. Without the standing
waves on the 300 ohm matching section, a G5RV would not work. The
transforming characteristics of a 1/4WL matching section depends upon
standing waves. The proper functioning of stubs depends upon standing
waves.

Cecil:

Don't even ask such a silly thing, happens all the time, here.

I just highlight, and then right click the post, of mine, which is in error. If using thunderbird (and I think you are), a menu will pop up, look near the bottom and find "Cancel Message", choosing that will create a popup which will ask you to confirm your wish to delete the message ...

Good luck ...

>
>I also swept our area 30 to 30 on HF with a not great hunk of wire and heard nothing beyond the normal ethernet, PC, printer and other office furniture. But nothing from the BPL which had a noticeable pattern.

Well, maybe you're right. Lets's do the math.

On Pg 54, Motorola says the power spectral density is about -50dBm/Hz.
If your receiver was set for SSB with about a 3KHz bandwidth, that's:
   -50dBm/Hz + 10log(3000Hz) = -50 + 34.7 = -15dBm
You should have been able to hear that when directly connected.

Assuming S9 is 50uv into 50 ohms, that's
   P = E^2/R = (50*10^-6)^2 / 50 = 125 uWatts = -9dBm
You should have seen noise at 6dB over S9 on your guess meter
(ignoring the 50/75 ohm mismatch and ham radio band notch filters).

>Shared bandwidth is an issue, but it is also split up by phase, and that helps somewhat.

Good point. However, even commodity DSL (1.5Mbits/sec) download is considered old technology by many broadband users. With 42.5Mbit/sec aggregate bandwidth, that would minimally supply 28 typical residential customers at 100% utilization, about double that if overloaded, and maybe one user doing file sharing. Splitting phases will increase that by x2 or x3, assuming there's no crosstalk between phases. That's more than adequate for residential service, assuming the building owner wants to pay for a T3 line or one third of an OC3 plus service.

I found 3ea X10 lamp modules and one controller. There are more buried somewhere.

>Hello, I have some doubts about standing waves on antennas that I hope
you could clarify!
As far as I understood, in a generic transmission line where we want
only carry power from a source to a load, we need to cancel the
reflected wave by adapting the load with the impedance of the line.
The result of this operation is S11=S22=0 and VWWR=1 that means no
standing waves.

"VWWR=1 means no doubled voltage.

As far as I understood, in an antenna we want to also avoid standing
waves by having VWWR=1 in order to avoid overloading problem to the
power stage...
>From theory I know that the best radiating condition for an antenna is
when it resonates, that is, when there is a standing wave� is that
correct?

Standing wave is if the electrons reflects from the end.

> How this condition is compatible with a VWWR=1 (no standing
waves) for a good antenna matching? Is there something that I�m not
catching?

You simply do not know Tesla's discovery. Transmitting antennas are the
electrons guns.

In poor antenna the voltage is doubled (at ends) and you have the standing
waves.

In perfect antenna electrons jump off from the ends of a dipole and the
voltage is not doubled.
Of course Tesla's antenna radiate the alternate electric field.

Doubtful it would work at all. Most CAT5/CAT5e/CAT6 cable is shielded
these days so it wouldn't make a very effective radiator.

Not in the Peoples Republic of California. I use quite a bit of CAT5e and some CAT6 and NONE of it is shielded here. In some countries (i.e. Switzerland) shield CAT5 is required. The only place I see shielded CAT5 is in industrial installations (high noise environment), and in some ham stations (RFI proofing). I've also used gel filled direct burial CAT5e which comes with a foil shield for the same price. The connectors are a bit more expensive, but I figure it can't hurt, especially when it's sharing the conduit with who knows what signal cables.

Most of the shielded CAT5 systems I've seen do worse with shielding than without. The problem is that the shields are usually grounded at both ends, creating the potential for a ground loop. I use SNMP statistics from the managed ethernet switches to determine if there's a problem. Isolating one end of the shield usually fixes it.

CAT5 is called UTP.  What does the "U" stand for?

Something else to think about that may help you understand:

Realize that if you connect a section of transmission line with one impedance to a section with a different impedance, you will in general have very different standing waves on the two sections. So, for example, if you connect the output of a transmitter to a 50 ohm line that goes for some distance, and that connects to a 250 ohm line that's an even number of quarter waves long, and at the end of that line there's a 50 ohm load, assuming the 250 ohm line is lossless, the 50 ohm line will see a 50 ohm load and have no standing wave. But the 250 ohm line has a 5:1 SWR.

Similarly, though the antenna conductors may have a large standing wave on them, they may reflect a load to their input, their feedpoint, that allows a low SWR on the feedline connected to that feedpoint.

You might think of the antenna as a "lossy transmission line," where its loss is (mostly) radiation. You can then see another example using just transmission lines...this time the 50 ohm line from the transmitter connects to a piece of 75 ohm line. The 75 ohm line is some even number of half-waves long, and it happens to have 7dB of loss -- maybe it's fairly small line, or is several wavelengths long. (In this case, the loss is as heating in the conductors of the line, not radiation as in the antenna.) At the far end, it's shorted, so the SWR at the short is clearly infinite. But at the end connected to the 50 ohm line, because of the loss in the 75 ohm line, the 50 ohm line sees a 50 ohm load, and the SWR on the 50 ohm line is 1:1. Note that along the 75 ohm line, the SWR went from infinity at the shorted far end, to 1.5:1 where the line connects to the 50 ohm line.

Cheers,
Tom

Try the "More options", to the right of your name at the top of the
displayed message.  There's a "remove" option in there, that doesn't
appear if you're not the author of the message.  I assume that will
delete it, though I don't actually have experience doing that, at
least not recently.

Cheers,
Tom

>CAT5 is called UTP. What does the "U" stand for?

UTP is Unmarked Tangled Pair
STP is Stiff and Tangled Pair

However, UTP and STP are the old designations. ISO/IEC 11801 has changed the designations:

Old	New	Screening	Pair Shield
UTP	U/UTP	none	none
FTP	F/UTP	foil	none
STP	U/FTP	none	foil
S-FTP	SF/UTP	foil or braid	none
S-STP	S/FTP	braiding	foil

Incidentally CAT7 will be where the 4 pairs are individually shielded.

I can rant on gel filled, UV proof, direct burial, riser cable, plenum cable, vertical tray cable, flat cable, and other CAT5 mutations if you want.

```

Hi to all

In EZNEC, when we want to get the near field datas, there is an option to enter the input power. So for a 2 kW PEP power, in order to obtain the V/m or A/m at a certain distance, should we directly enter 2000 W in the input power window, or should we transform it to the effective power 'RMS' value of 2000/sqrt(2) = 1414,2 W, and then enter 1414,2 W instead?

Thanks for your help

de Pierre VE2PID

You can get a free email account here:

http://gmx.com/

You can then use that email acount to get a free post/read account here:

http://eternal-september.org/RegisterNewsAccount.php

You will be back in business with tbird and an email that people can
spam from here to high heaven, without worry ...

Just in case you are interested ... good luck, either way.

--

Regards,
JS

If you don't want want to mess around registering for the news server or getting a throw away address, you can use the free nntp.aioe.org. Just plug it into TB or any newsreader and away you go. There are more restrictions than eternal-september but if you have a life other than Usenet they won't bother you...

Hello once more. One last thing to add is that even if one installs a high-gain Wi-Fi antenna, depending on the distance to the source, you probably won't have clear line-of-sight and subject to multipath problems. The network might show a "4 green bars" signal strength one moment and be yellow, red, or out the next). Sincerely,

--

  I'm definitely using a less than scientific method, so don't take my
estimation as solid proof.  It is just a guess at best.

Michael

```

This Lazy H is specifically made for 10 meters, the summer Sporadic E season, and the steadily climbing solar flux. I almost never use 20 meters.

Michael
KS4HY

Thank you Irv, for the nice words you posted about me. I was fortunate
to have been an antenna engineer with RCA for 31 years, where I was
surrounded with professionals who were in the top echelon of antenna
developers. I've had no other formal training in engineering other
than my close association with them, and studying their voluminous
text books. Learning as a ham (78 yrs continually licensed since 1933)
is clearly the root of my engineering knowledge.

Do you have a copy of my book, "Reflections--Transmission Lines and
Antennas? If not, some of the chapters from the book are available for
downloading at my web page at www.w2du.com.

Thanks again, Irv,

Walt, W2DU

I used to have a 1 watt USB dongle, came from china ...

I am thinking you might still be able to locate one on ebay?

Anyway, let me know what you find.  I am going to be setting up a long
range link in the near future, for a friend.

Regards,
JS

Do you have a copy of my book, "Reflections--Transmission Lines and
Antennas? If not, some of the chapters from the book are available for
downloading at my web page at www.w2du.com.

Thanks again, Irv,

Walt, W2DU

Wow! Impressive resume Walt. It's funny you should ask about 'Refections'.
I never had the book, but did download

and study the available chapters from your website.

Due to some pretty serious illness and surgery during the past two years I had to sell my house. At the same time my prognosis was so limited that I gave away all my equipment, tools, parts, and books -- most of it to other hams as well as our local radio club. I had more antenna books than anything. We never dreamed I would be in condition to operate a station again and it wasn't easy giving up one of my great loves in life -- HAM RADIO!

As per Murphy's Laws, my recovery was remarkable, but I had to move into a seniors residence where nursing assistance was available, and since then I have had restorative surgery and am in pretty good condition again. I am now ready to resume my participation in the hobby, but in a very downsized manner. I just bought a Yaesu FT-817ND (an all band/mode QRP rig, the only rig I ever bought brand new) and am in the process of building a magnetic loop antenna which I can cleverly conceal on my balcony. Basically it is a very simple project, considering the fact that I will be operating either 5w or 2.5w and do not have to go overboard on a HV tuning cap. I've always been a low power operator, knowing that with a little operating skill, and a 'decent' antenna you don't need a lot to have a bundle of fun. The snow has just cleared from my area (Calgary, Alberta) and I should be up and operating pretty soon (as soon as I can concoct a simple insulated coupling between the tuning cap drive motor and the capacitor). The principles of the magnetic loop are simple, and I have been able to download lots of good hints and kinks over the net -- more than I need.

So I'm a long way from dead, and looking forward to resuming the hobby which has kept me fully occupied for many years.

I've helped many fellow hams with invisible antennas -- now it's my turn and I'm approaching it with a very optomistic outlook. Starting over is not difficult -- once you have the knowledge, the rest is easy. Maybe we'll meet around the bands someday.

Thanks again for all you've given to the hobby! Ohm's Law was easy, but we needed folks like you for the antenna understanding.

Irv, VE6BP

I appreciate the reply, it seems my Alfa � watt [bs-rating= 1/10 watt] is making the grade with 4 access points reliably so it's just the little boy ego in me that seems spoiled when 110 access points are showing up and only a handful can hear me. Then again it's real crowded here and channel bleeding or some other 'Over crowded' phenomenon is dissing my male ego. I sort of feel like a dumb truck driver running 1500 watts to talk to the driver behind me9 In respect to the industry and moral conscience I do not want to splatter my neighbors with a gazillion watts and make their 5 bar connections slow because of me and rf splatter. You guys know so much more then I it isn't funny, don't want to sound like a moron but this "Dish" theory is a hidden treasure right under everyone's nose and it amazes me that just putting a retired Dish Network disk 13" behind the Alfa USB WiFi with the 3 DB gain Vertical ground antenna on it gives me a 5 bar signal from what used to be a 1. The reason I am picking on this one AP is that I have the owners blessing to use it, so why not focus on the legal one. Sure I am willing to hack a stranger's one if I have to, but here is a case where I don't, so I won't. But up till now his signal was week, now it's good, but experimenting with the other unsecured AP's there are some that are 3 bars and can not get a handshake for more then 10 seconds at 1 MBPS
Then PWAfffffffft!!! I am bumped off then on then off then on�
Weird I say.
But it has all the symptoms of an Elephant base station, all ears no mouth, and I am Irish I don't take custom to things that way, generally the other way around LoL.
But I don't want to be a CB Rambo moron and ruin it for everyone else; I am on line at a steady 54 MBPS right now so why bother. Just Ego I guess or interest in the science maybe. By the way the Dish is Indoors!!! I used to be a HAM, tech license but let it laps years ago. Can't stand the FCC's attitude.

I appreciate the reply, it seems my Alfa � watt [bs-rating=
1/10 watt] is making the grade with 4 access points reliably
so it's just the little boy ego in me that seems spoiled when
110 access points are showing up and only a handful can hear
me. Then again it's real crowded here and channel bleeding or

some other 'Over crowded' phenomenon is dissing my male ego. I
sort of feel like a dumb truck driver running 1500 watts to
talk to the driver behind me! In respect to the industry and
moral conscience I do not want to splatter my neighbors with a
gazillion watts and make their 5 bar connections slow because
of me and rf or binary packet splatter/collisions. You guys
know so much more then I it isn't funny, don't want to sound
like a moron but this "Dish" theory is a hidden treasure right
under everyone's nose and it amazes me that just putting a
retired Dish Network disk 13" behind the Alfa USB WiFi with
the 3 DB gain Vertical ground antenna on it gives me a 5 bar
signal from what used to be a 1. The reason I am picking on
this one AP is that I have the owners blessing to use it, so
why not focus on the legal one. Sure I am willing to hack a
stranger's one if I have to, but here is a case where I don't,
so I won't. But up till now his signal was week, now it's
good, but experimenting with the other unsecured AP's there
are some that are 3 bars and can not get a handshake for more
then 10 seconds at 1 MBPS
Then PWAfffffffft!!! I am bumped off then on then off then on�
Weird I say.
But it has all the symptoms of an Elephant base station, all
ears no mouth, and I am Irish I don't take custom to things
that way, generally the other way around LoL.
But I don't want to be a CB Rambo moron and ruin it for
everyone else; I am on line at a steady 54 MBPS right now so
why bother. Just Ego I guess or interest in the science maybe.
By the way the Dish is Indoors!!! I used to be a HAM, tech
license but let it laps years ago. I can't stand the FCC's
attitude. Somewhere in the registry setting I can set the
"TimeToLive" string to 128 ms is that what you mean?
I know IP stuff [it's my dreaded job] but the microwave stuff
you guys smoke me.

Kaz <rowdy1970.UCE@hotmail.com> wrote in news:lItKg.930$I71.63@trnddc01:

> I am looking for an easy way to convert a standard DISH TV offset feed dish for WIFI use. I desire to mount this thing on the rooftop for a long distance rural link. I need to understand if it would be easier to go the USB device route or what the ramifications are to going the traditional rf and coax route? I think my install will require around 60 to 75 ft of feed line. Could I use a wifi "extender" amplifier at midpoint to get past feedline losses? If I go the coax route, what would be an easy way to feed the dish? Could I use a tiny off-the-shelf external wifi antenna inside of a can or do I need to homebrew something more extravagant?
>
> If I go the usb device route to feed the dish, how can I extend that far?
>
> I do need to connect this to a pc as a NIC or client, therefore remote mounting a router wont do the job for me.
>

Well I'm no Ham Pro but Network stuff I can help. You can USB to the dish up to 75 feet BUT, you have to interrupt the line run with a USB hub before you reach 30 feet, and for Geeky reasons I don't understand I have been told that NEVER put the interrupting USB hub evenly in the middle of a run. Sounds like you need 2 hubs, each at about 25 feet of USB cable. Or; if you can get to just under the roof in the attic use a HUB at 25 feet, and then a HUB at almost 30 more feet put a cheap Alfa WiFi USB dongle � or 1 watt model [about 70 bucks] Just under the antenna, then run 10 feet of the 400 Microwave cable from the Alfa to the feed horn of the dish. 3 db loss at ten feet. I am using the 3 DB gain Vertical ground that is popular with the Alfa USB dongle indoors so it's located AT the feed horn itself, but in your case the semi USB to near the dish then a RF cable short run for the antenna will keep the Alfa unit out of the weather. The Alfa watt ratings are crap; I would do the 1 watt model if you want at least 300 miliwatts out.

My � watt model is struggling to be heard, so 3 bar signals it can hear but the AP's can't hear me as well [I think]. Could be channel bleed though. If you wanted a lesson on FCC law you would have asked so I wont go there [to much] and as you know by my previous posts I don't care, but for your own good be aware you may be pushing the limits. Unlike me if you have a HAM ticket that could be a problem if you get caught. I'm not big on POWER drunkenness anyway, sensitivity and narrow RF beams make more sense and displays intelligence. And the challenge is fun ;-)

You indicated that you're working other repeaters with ease. Blaming
the trees sounds right.

I think a 2m beam is the way to go. I've used one at Field Day for
ten or so years from south of San Diego and easily worked 100 miles
into Los Angeles, simplex, obviously. The improvement in performance
is dramatic with 15 dBi gain, compared to approx 2 dBi gain of an end-fed dipole, your j-pole. My two beams were less than 50 dollars
apiece at ham swap meets. Mount with elements vertical.

I just did an experiment and, as I expected, a 10 dB increase in
signal strength took me from unreadable to Q5 copy with tolerable
background hiss. (I used switchable attenuators to set up the signal
test conditions and a distant repeater as the test signal.)

If the repeater is no worse than "barely readable," 10 dB should fix
you up.

By the way, the gain effect is not so great that you'd lose the other
repeaters, unless one just happened to hit a deep null by bad luck.

"Sal"

Final verdict on the center fed Lazy H antenna for 10 meters...

I really wanted to like this antenna. I really wanted it to work as stated in the various handbooks. I have checked and re-checked the measurements, and I have double checked the connectivity to make sure the top and bottom elements were being fed in phase. The bottom left element was connected to the top left element. The bottom right element was connected to the top right element. I have done countless A/B/C test with a dipole, an extended double zepp, and the Lazy H all broadside to the same direction on 10 meters. This antenna was specifically cut for 10 meters, and it was installed for horizontal polarization as shown in the ARRL handbook at heights of 40 feet and 50 feet at the top wire. I double checked everything, but the final verdict is not what I had hoped.

Here it is;

In the real world on 10 meters the Lazy H antenna with four half wave elements on 10 meters (two collinear elements on top and two collinear elements on the bottom), half wave spacing between the top and bottom horizontal elements, center fed with 450 ladder line all the way back to the antenna tuner, using a 450 ohm ladder line phasing line to connect the top and bottom elements with no twist was consistently out performed by a 10 meter extended double zepp facing the same direction even when the Lazy H antenna was given a 10 foot height advantage over the extended double zepp.   On many occasions the Lazy H was also out performed by the 10 meter dipole dipole. I have not tried the end fed Lazy H design with the 1/4 wave matching stub and the 180 degree twist in the phasing line.

On a positive note, the extended double zepp antenna with a 450 ohm matching section down to a 1:1 balun and then 50 ohm coax is a solid performer, and it consistently out performs a dipole and the Lazy H broadside to the antenna.

You are "matching" 450 ohm line to 50 ohm coax thru a 1:1 balun?

Where is the matchbox/tuner located?

Never mind, should have read your post closer, you are claiming to have
already handled it in the "450 ohm matching section."

probably because it is unbalanced by being connected:
>to the antenna tuner
which through its ground connection unbalances the Lazy H.

For the entire duration of your discussion, I've seen no treatment for
common mode problems that you have described by various symptoms in
the past. Your complaint of poor performance is a chief indicator.

Other indications have ranged variably from glaring beyond that to not
apparent yet remaining a problem still, as is obvious by the poor gain
performance for all variations.

You already have the solution in the other antenna:
> a 1:1 balun and then 50 ohm coax is a solid
>performer
provided the BalUn is a W2DU.

Your problem is NOT the antenna!

Merely *attaching* something to the non-Exclusive Use common
area of a condo property can be prohibited by the homeowners
association. It is like someone tying something to your car - he can
claim that it isn't a *permanent* attachment, but you'd be legally
correct in requiring its removal. The surface of a patio, on the other
hand, is *meant* to have things set on it, and so setting a tripod to
hold a dish cannot be prohibited on other than safety considerations
(and perhaps also on historical site considerations).

Suspend a heavy object from a rope over level ground. If I have plugged
in the correct numbers, the repeater will be on a line drawn by the
shadow of the rope at 12:55. That is, the repeater will be directly
below the sun at that time.

Maybe you can get an idea of the path to the repeater that way.

Well, I have applied some numbers today and I am changing my mind that
the trees are not the problem.

If my numbers are correct: The repeater, 19 miles away, is 1900 feet
above his elevation. At that distance, the antenna will appear be about
240 feet lower than actual due to earth curvature. That makes the
antenna appear to be about 0.954 degrees above the horizon.

That is equivalent to 60 feet at 3600 feet. In other words, 60 foot
trees closer in will be completely in the way. The hurtful part of this
is that his antenna at 45 feet will have a lowest angle of radiation
(take-off angle) of .7 degrees, right into the near trees. The next lobe
above that is at 2.2 degrees. Between those two lobes is a null.

In short, I think his antenna is in a null. I think the only answer for
his present situation is to raise the antenna another 10 feet.

What do you think?

73,
John

Clever trick, but methinks I have an easier way. I've sighted 1 degree beamwidth microwave dishes this way:

1. Place a road map on a flat surface[1]. If you can't find a road map, print a Google Maps or equivalent road map on a piece of paper[2].
2. Pound a nail or push pin into the map at your location.
3. Find a distant mountain, that's also visible. Pound a nail into the map at its location and sight between the two nails to the distant mountain.
4. Without moving the map, find the distant repeater location on the map and pound in a 3rd nail or push pin.
5. Sight from the nail at your location, to the nail at the repeater location. What you see is where it's located.

[1] Yes, the earth really is flat.
[2] When I didn't have a printed map handy, I've used my laptop LCD screen and 3ea flat head screws.

Easier than what I suggested? Actually, all he has to do is step outside
at 12:54 and look at the Sun's location. (I admit it is more accurate to
do this in the winter.)

I am afraid I cannot tell whether items [1] and [2] are just screwing
with me or that you are sincere.

John

Hello John,

This link:
http://www.tetech.nl/divers/Kirk_Repeater_USA_1.png
shows the path profiles with and without trees (from Radio Mobile, VE2DBE). I will keep it there for some weeks.
I used 30m (98ft) high trees (so they are easy to see).

The trees cover some additional part of the first fresnel zone, but the average canopy will be lower and the absorption loss is not that high at 146 MHz.

So yes, there is influence from the trees, but not that much I think.
If you want to get some increase in signal, you need to remove lots of them, and he don't want to do that. Note that the first trees are 160m away from his antenna (info from google earth, based on data provided by Kirk).

With kind regards,

Wim

The tuners I have both have built in baluns. After I took down the
Lazy H I put up a delta loop with 300 ohm twin lead back to the same
balanced line tuner connections.  The delta loop out performed the
dipole by a hair, but the delta loop has a height advantage over the
dipole.

I have some other baluns lying around.   I suppose I could hook the
450 ladder line to one of those baluns and then connect a coax jumper
between it and the antenna tuner and try it.  It seems like they may
```

be W2AU baluns. I bought them back in the 1990s, but I have not looked
at the labels in awhile.

I still may try the end fed Lazy H with the twist.

Michael

Well, your method only works at exactly 12:54PM, requires remembering daylight savings time, requires dark glasses to avoid blindness, works badly in fog, need to get it right the first time, and offers no way to document the results. At 12:54PM, the sun is almost directly over head with no point of reference, as you would have at the horizon. Manually translating the sun's overhead direction, to azimuth at the horizon, requires considerable guesswork. A plumb line might helpful.

Incidentally, trees are a very real problem with antenna sighting:
<http://802.11junk.com/jeffl/pics/DBS/index.html>
That's my view of the DirecTV bird at 101 degrees. The photos were taken during the bi-annual solar outage, where the sun gets behind the satellite belt.
<http://en.wikipedia.org/wiki/Solar_outage>
Note the branch shadows on the dish, which are blocking the signal.

>> [1] Yes, the earth really is flat.

As far as this measurement is concerned, the earth is essentially flat over fairly small areas. No spherical geometry required. Even the United Nations has adopted the flat earth map for its flag.
<http://upload.wikimedia.org/wikipedia/commons/2/2f/
Flag_of_the_United_Nations.svg>
Antarctica is a collection of icicles around the outer edge.

The 2nd item is for real. I was on top of a mountain, trying to aim a dish without a map. I had Street Atlas USA v5 on my then ancient Toshiblah 100CS laptop, which I used for my initial bearing. Other than having a difficult time holding the laptop, problems viewing the screen in the sunlight, and too short a base line, it worked.

Thanks and not a problem. You have a long way to go before such comments become a problem.

I just remembered most of those external baluns are 1:1 baluns. I do
have one external commercial 4:1 balun, and one 4:1 balun I hand wound
from a schematic in one of my antenna books.

-Michael

A net book and managable wireless switch running a stable
version of Linux might work,
But a programmable router would be better, especially one that
has a Linux os and is Hackable. Here is an interesting video
that makes a run of the mill Lynksys 80 dollar router do what a
Cisco AirNet 2400 can, Repeater and all, they hack the OS and
install their free to public home brew features.

http://www.youtube.com/watch?v=08eVqpPVGiU

So much for spending 600 bucks if it works, you'll be under a
hundred.
Personally I am lazy and employed; I would just go out and buy a
Cisco or other top end product and be done with it.

A separate computer running at the base of a big antenna? I
wouldn't want that on a cold winters night and the snows coming
down etc...

That is most likely where my problem is. Remember this is just a redneck style Git'r done solution till my commercial one arrives, a vertical anttenna in front of a dish has got all ears and no mouth written all over it.
Now if I was using a feed horn [cantenna type] well that would prove tx power and your sugestion as well is the culprit, we know the clutter thing is in there because this whole shmoosh is indoors. I hate running high power $$$ and frequent burnouts of the finals. I like to think a half watt is all I'll need. Now if I can get my TX to look like a Laser beam hey hey.

Seriously check this out;
www.youtube.com/watch?v=piFISJKyV6c
www.youtube.com/watch?v=weEZtBTfEMU

The software is free but I preffer the USB dongle os running BackTrack 3 It's a bit simpler, and you need 2 wifi dongles, prefferably the Athros as suggested, II use them on other versions of Linux too, they seem to be the best for hackin around, they are permiscuos and can Inject packets to an already busy data streem thanx to the MAC address spoofabilty they have.
You can also use this software to turn a laptop with two dongles into a covert repeater. But expect downtime with that idea.
You can Cache everybodys WEP keys buy faking your IP as one of the AP points in the Air. Send all 'packets copy' to a data BIN folder and run the desypher software built in to get the wep, wpk and such. Even SSL ports. It's my job to keep these script kiddies out of my network, I have to know this stuff.
Our wireless Credit card system is constantly under attack by NIX kids [wannabe hacker teens running linux] As long as I can crack it, they will not use it, it's sitting there off line collecting dust per order ME!! WEP is not safe neither is WPK, though a data base dictionary service is needed for WPK sometimes for 25 bucks these hackers will take your glop of ssl data and within 1 day send you the security key.
This is the nightmare behind CLOUD computing, the access to several hundred micro proccessors to crack a key is now CHEAP, I use 40 lab machines to convert and crunch a DVD 2 hour video in ten minutes with cloud computing software. It's realy FARM computing not quite the same as the term local ads are running

such as google is now cloud computing.
Unfortunatly Criminal minds are more intrested in this more
then we are.

http://www.youtube.com/watch?v=08eVqpPVGiU

So much for spending 600 bucks if it works, you'll be under a
hundred. Only 235 milliwatts max though.
Personally I am lazy and employed; I would just go out and buy
a Cisco 1/2 watt or other top end product and be done with it.
Can't use a whole watt if you woryy about FCC dudes lurking
around, that and a 30 db gain your way over limit.
Too bad these little routers do not support PoE [Power over
eithernet, you can use a power injector [40 bucks] to send the
power to the router through two of the 6 conductors of the
CAT5 cable.

For now just run a cat 5 cable and low voltage power supply
bell wire to the router witch HAS WiFi 2 channel built in.
Check and make sure there are External Antenna outputs on this
otherwise walk away from it. Soldering 2.4 GHz equipment
___s#$ks. If I didn't own a 1300 dollar wire bonder unit I
wouldn't try it, but fortunately I do and the job still stinks
, If your not a neat freak with connections you have sporadic
rf leaking everywhere.

google 'network stumbler' , it's freeware or actually "BEG"-ware
but it works most the time.
I here there's a few WalMart craptastic USB dongles that will
not work with it but thats a rare synptom.

Be extreeeeeeemly carefull here, I know you said DC load tested
the antenna but was it unplugged?  More then once in my younger
dumber days I sent the voltage comming out of the Volt meter
[digital] hap hazardly into the final output of the radio, that
was more then enouph to poof the transmitter chip, now it's
toast. I would never believe the amp/volts comming out of a
small digital test meter would roast the finals, but it did.

The insanity of it being a crime to receive any radio signal is so
obvious, I can only consider those recognize it as a VALID crime are insane.

However, I have always felt the same, and since a VERY young age, that
making the growing or possession of plants a crime demonstrates EXACTLY
the same brand of insanity.

If you look around, you will find other examples of this same insanity ...

The insanity of it being a crime to receive any radio signal is so obvious, I can only consider those recognizing it as a VALID crime are insane.

However, I have always felt the same, and since a VERY young age, that making the growing or possession of certain plants a crime demonstrates EXACTLY the same brand of insanity. The men/groups/etc. establishing themselves as rightfully being able to command such insanity must think themselves GOD, how nice!

If you look around, you will find other examples of this same brand of insanity ... and, if you look even closer, you will find it usually involves a law which allows some to become very rich from its' enforcement ... so that in the end, those having the laws forced upon them are forced into participation in the insanity! As, even the simply actions to resist those laws, and even solely on principal, brings one under great scrutiny, or even punitive actions! And, this seems to have a 1:1 correlation to the "money stream(s)" generated by the law(s.)

But, has little to do with lossy coax at high frequencies ...

The answer is diversity reception, so you don't get nulls where signal is
lost.

Brian

Usually inverted "F" !  Most have two, sometimes one is vertical and the
other horizontal.

In that case, perhaps it is due to his antenna being at a height that
puts the target into a null. Along with low repeater output power, I

suppose that could cause it.

Thanks, Wim.

Anyone know where I can find a dual band 2 meter 70 cm beam ?

Trying to build a beam for both band and I want to put it on 90 degre =
rotor=20
to make it work in horizontal and vertical so I would need only one coax =

line for 2 m v/h and 70 cm v/h

thanks..

Ok. Might be a sick repeater. That would explain quite a bit.

>I have been out of HAM radio for about 15 years so am having to relearn
>quite a lot. Had a brain injury, doh!, so lot's of what I knew went bye
>bye. Lot's of holes in the memory.

I have a slight idea of what's that's like. I had a triple bypass
operation in 2002. They're not sure what happened but the result is

that my memory around that time is like Swiss cheese. It's a mix of things that happened that I don't remember, and things I remember that never happened. Fortunately, things got better after about a year for me. Hopefully, you'll do as well. Also, my neighbor had a brain tumor removed. She's fine, but has the same scrambled memory problem.

I gave up ham radio from about 1975 to 1992. I was working designing radios and working in commercial 2way. The last thing I needed was ham radio after hours. Welcome back.

>I will find out about the repeater
>during the next club meeting. Specs and all.

Good idea. I assumed that you had already done that. If the specs on the repeater (tx power, feed line losses, antenna gain, antenna height, lat-long) were known on the repeater, I can calculate the signal strength you should expect at your end.

Anyone any experience of nesting hentennas for multi band use? I'm thinking of a 6m hentenna inside a 10m one.

My first thoughts are that it should work, like nested cubical quads.

That is always a possibility, Dave. I have seen similar situations and I am not surprised at your findings. It is one reason I suggested moving his antenna, even slightly.

His latest post may also indicate that there is a repeater problem. So, I hope he posts his findings after his meeting with his club.

Cheers,
John

> better than this.
>

The results are all over the map.  A piece of Cable TV cable might not
be a bad choice, if you can scrounge one. The 75 ohms probably isn't a
big deal.

At 144 MHz, bigger in diameter almost always beats fancier dielectric
(that is, the .405 inch RG-8, RG-213 flavors will usually beat any of
the quarter inch cables (RG-6, RG-8X, LMR240, etc.) because dielectric
losses aren't a big driver.. it's the IR loss in the center conductor.
  RG-11, for instance, has less than 1.2dB loss for a matched 75 foot
line, and for the 1.5:1 mismatch, the loss only goes up 0.1 dB.  (RG-11
type coax has a solid dielectric, and is pretty darn rugged stuff)

75 feet, at 144 MHz
LMR240 - 2.2 dB
Belden 8215 (RG-6A) - 2.5 dB
Belden 9258 (RG-8x) - 3.0 dB
Tandy RG-8x - 3.1 dB
Belden 8267 (RG-213) - 1.9 dB
Wireman CQ110 (RG-213) - 1.6 dB
Belden 8237 (RG-8) - 1.7 dB
belden 8213 (RG-11) = 1.2dB

Elk makes a 2m/70cm dualband log-periodic beam.

http://www.elkantennas.com/

I keep one in my ARES/RACES go-kit setup... portable, easy to set up
and tear down, very useful for field deployments out in fringe-
reception areas.

Huh? 75 ft of RG-11 has almost 8dB of loss at 146MHz. 75 ft of LMR240
has 9.7dB of loss at 146 MHz.

I won't go through your entire list.

Check out http://www.vk1od.net/calc/tl/tllc.php

Cheers,
John

John you need to see where you went wrong. The numbers Jim listed are either correct or very close. I did not bother to do the calculations, but looking at a 100 foot chart, the numbers are very close and no where near the numbers you have.

I thought you may have looked at the web page and missed it defauls to meters, but that does not seem to be the case to me.

You are correct, Ralph, and I apologize to the group for my error. I did
```

indeed put meters rather than feet into the calculator.

Again, my apologies, and thanks, Ralph, for correcting me.

Cheers,
John

I have a Heath HM-2102 VHF SWR meter 50-160 MHz
0-25 and 0-250 watts. Excellent condition.

I'm *asking* $40 plus shipping.

It can be viewed at:

http://home.comcast.net/~hsknoll/site/?/photos/
&PHPSESSID=29ec62ea0bf1fe4d25e318b011cf0bbf

or

http://tinyurl.com/yktwxpz   click on photo to enlarge it.

It is mounted on an angle bracket about 12" from a mast 20' above my
metal roof. The mast is isolated from roof but is not yet grounded.

My spacer basically disintegrated. I replaced it with 1/2" pvc pipe. I
measured the spacing at the base and got it as close as possible.

I will check out the other connections. There is obvious aluminum oxide
on the assembly so it is very possible it is down between the parts.

I'll get up on my steep metal roof after the rains stop. :-)

That's what I used..
Sure you got feet and not meters?

B9219, 75ft, 146 MHz = 1.811dB

Yes, Jim, Ralph pointed that out to me yesterday and I posted an apology
to him. I see that I should also analogize to you for my mistake.

Thanks to you both.

John

I have a Heath HM-2102 VHF SWR meter 50-160 MHz
0-25 and 0-250 watts. Excellent condition.

I'm *asking* $40 plus shipping.

It can be viewed at:

http://home.comcast.net/~hsknoll/site/?/photos/
&PHPSESSID=29ec62ea0bf1fe4d25e318b011cf0bbf

or

http://tinyurl.com/yktwxpz   click on photo to enlarge it.

Darn newsreader that didn't have all the messages loaded.. I saw Ralph's comment and your reply. Such is life..

Now, if you want some high loss coax.. can I interest you in some tiny coax made of stainless steel? It's for cryogenic applications so it has very, very low thermal conductivity, but it also has really high loss. I don't think you want to be running kilowatts (or even watts) through it.

Well, thanks, Jim, for your kind offer. However I have plenty of lossy
cable now. I only use in the lab because other options are difficult to
handle.

Cheers,
John

According to the loss calculator at Times Microwave the loss at 144 MHz
for a 75 length of LMR 240 is 2.952. 100 METERS is 9.687.

Perhaps you misread.

Not a Sea Story and relevant to my learning an important multipath lesson:

In 1974, I was on an aircraft carrier at a pier in Long Beach Shipyard. Ship's TV sigs not so good, so I ran a cable from the CPO lounge TV out and up to a flight deck catwalk.   On the catwalk, I mounted a small all-channel antenna on a mast strapped to the rail. The transmitters (Mt. Wilson) were located away from that side. All very good pictures. In about two months, when the ship moved into drydock, it was turned 180, so I rotated our TV antenna to compensate. No good. Signals arriving across the flight deck were all awful. Unwatchable.

I suspected reflections from the flight deck, so I moved the antenna all the way aft, where it was receiving through clear air again. Bingo! Even through the added 150' of cable I needed, we got our nice pictures back.

Im convinced that my J antenna that I used while camping radiated
mostly verticaly. The situation sounds very similar to yours. I
couldnt hit the repeater back home with 50 watts using the J- while
my wife could make contacts on her HT on the same repeater, Her
antenna was either a telescoping .5 wl or 5/8 wl connected directly to
her HT.

Jimmie

Assume a non-reactive antenna. Start with a half-wave dipole.

What is the radiation resistance and what is the terminal resistance?

Thanks,
John

Hello Kirk,

I sent you a PM with a result from Radio Mobile.

It took a long time to get RMW working, and getting the terrain data into the SW.

It is 10 years ago that I used RMW and that computer I don=92t have anymore. I had to start from scratch. First checked with Dutch terrain data to see whether the results are meaningful.

When you look to the path profile, you have a huge margin (received power -76 dBm). I used 10W into a 2 dBi antenna (on both sides). I attached the path profile as generated by RMW (Personal Mail only).

Even reducing your antenna height to 1m AGL gives sufficient margin (Prx -86 dBm). I used 30m AGL for the repeater antenna. You have 1 degree elevation towards the repeater, that is huge (we don't have that in the Netherlands).

Assuming the data is correct, it is really strange that you can't hit the repeater. I couldn=92t find were to set vegetation and cities, but even this shouldn't be a problem. I hope some other people can confirm the results from RMW.

With kind regards,

Wim

Hey, Kirk -

After reading Wim's response, I am more convinced than ever that you
have a problem with your antenna, coax, or transceiver.

What type of coax are you using? Could it have gotten water inside? Are
you using the coax that you used 10 years ago?

Try to think of other question similar to these and we'll get to the
bottom of this.

Cheers,
John

Radiation resistance can be, and is, defined differently by different writers. Often the term is used without clarifying definition, and of course that leads to trouble. Beware any time an author throws around "radiation resistance" without carefully defining how he means it. There's a nice section (section 17; page 118) on it in King's "Antennas" chapter of King, Mimno and Wing's "Transmission Lines, Antennas and Wave Guides." I highly recommend reading that passage, though I know that not everyone likes King's writing as much as I do. (I may be able to supply a PDF of it, if you can't find the book.) Generally, radiation resistance is associated with power actually radiated by the antenna: i^2 * R(radiation). One possible definition is "that portion of the resistive component of the feedpoint terminal impedance that represents radiation." But when the feedpoint is not at a current maximum, "radiation resistance" is sometimes (often?) taken instead to be the resistance which, when multiplied by the square of the current at the current maximum, would result in the value of the radiated power.

Presumably the "terminal resistance" is the resistive component of the impedance seen at the antenna's feedpoint terminals. It's generally a good idea to specify that the current is the same magnitude and opposite direction in the two feedpoint terminals, and that they are closely spaced--a tiny fraction of a wavelength apart.

The difference between the two represents power dissipated in the antenna itself. Of course that's generally a pretty low percentage of the total in self-resonant antennas, but in short antennas (loaded dipoles and monopoles, and tuned loops that are very small compared with the wavelength) the power lost in heating the antenna and associated loading reactances can be significant.

Cheers,
Tom

Orfanidis has an explanation in Chapter 15 of his online electromagnetics textbook
http://www.ece.rutgers.edu/~orfanidi/ewa/ch15.pdf
page 612

Not a very complete discussion, as might be found in Kraus, but at least it's online.

There's also Prof. David Jeffreries's website
http://personal.ee.surrey.ac.uk/Personal/D.Jefferies/radimp.html
"The classical way to calculate the radiation resistance is to surround the antenna with a hypothetical closed surface in the far field, calculate the values of electric field and Poynting vector on this surface in terms of the antenna terminal current I, integrate the power flow per unit area, represented by the Poynting vector, all over this surface, to determine the total outward travelling power in watts, and equate this power to the quantity II*Rrad/2 as discussed above. "

Thanks, Tom. That pretty much answers my question.

Thanks also to Jim.

73,
John

John,

I believe it is either the trees or the antenna. The coax is new and the transceiver worked fine last time I used it. Also works fine with this setup getting into the repeater on Schweitzer , 145.230, with 5 watts and the signal report from a gentleman I spoke to was 59. That is a clear shot and a few miles closer. Although the profiles show there should be a clear shot to the .780 repeater I can gurantee there is a wall of trees on the first little ridge on the profile. I found that my club, which I've only been with for a month, has an SWR meter and an antenna analyzer. I hope to borrow them to see what's up. In the meantime I will pull the J-pole down and clean it up as suggested. There is considerable aluminum oxide on the outside of the parts so there may be some between the base and uprights. When I put it back up I will move it 180 degrees from it current location. That will only move it about 2' but who knows.

Are you pointing to the trees that are about 160m south of you and
below (that are also visible in google earth)?

If so, I can't  believe that this will put down your signal from about
-76 dBm towards unreadable (so in the -117  dBm range). Reason: the
first Fresnel zone has a diameter of 36m (118ft) at 160m (525ft)  from
your antenna and I don't expect all trees are over (for example) 20m
(60ft) height.

>=A0I found that my

I may have missed it, but have you tried riding around with a mobile rig and
seeing if you can hit the repeater ?

A SWR meter may not tell you much about the antenna. I think you are using
rg-8x. The coax will have enough loss at 2 meters to give a very low false
reading. YOu can probably unhook the coax from the antenna and only show
about a 3:1 swr.

Of course. It all makes sense now. Feeding a 1/2W dipole in the center causes one to measure approximately the Rr. However the dipole can be fed at some other point. Even fed at one end where the feed point resistance can be in the hundreds to thousands of ohms.

So, radiation resistance is a convenient device (along with current at that point) that we use to represent power "lost" from the antenna through radiation. Good. I can understand that.

Gotta be very careful of the definitions. It was in Kraus' Antennas For All Applications that raised my question.

> Presumably the "terminal resistance" is the resistive component of the

I understand.

That, too, is understandable.

> Cheers,

> Tom

Thanks again, Tom, for this.

Also, I understand Jim's reference to integrating the volume to get the radiated power and, hence, Rr. Thanks, Jim.

Cheers & 73,
John

The antenna itself could not have radiated a significant percentage
vertically if used near the design frequency. It is effectively a half
wave vertical if properly constructed and fed. Fed being the most critical.

If you didn't choke the coax properly and it was parallel to the ground
you may have radiated some towards the zenith. But I doubt it was most.

tom

Blah de blah

How many amateur radio operators use this kind of academic preening
when they are putting up a dipole.

Too much hand-waving here to be useful to most folks.

The Cushcraft A3S beam has 3 elements. The driven element is setup to
be used as a rotatable dipole on 40 meters. It works a lot better than
it sounds.

The spacing of the elements on the boom does not change.

Thanks.

Between the Rotor and the A3s/ and the Dipole getting it up to 40ft should be a
real pain.

Hello Kirk,

Did you receive my PM with the path profile and propagation
prediction from RMW?

I now added clutter because of trees (I used 30m high trees with 80%
density). The predicted signal strength goes down from -76 dBm to -81
dBm (10W transmitters into 2 dBi antennes, your height 10m, repeater

heigth 30m).

Jeff (AE6KS) sent me a .kml file with the path profile from you to the repeater on the hill, there is good agreement between the data I used in RMW.

So before going to the paper/plywood production plant, you may search for some other problem.

With kind regards,

Wim

Hello,

After 10 years I started again with Radio Mobile mapping and propagation prediction program. One can export path profile data via the "Radio Link" calculation pane. The result is a text file that you can modify (to change the path profile).

Is there any possibility to import a modified path profile again, so that a new propagation prediction simulation can be done

With kind regards,

Wim

It is about the same size & weight as other multiband beams. The 40 M
add on seems pretty expensive but I do use it a lot.

Also, Mine is mounteds on a tilt-over, crank up from the late 1970's.
Two electric winches, no sweat for an old man.

Also, there is a Homebrew tilt mechanism...

You can check it out at
http://dixienc.us/TiltOverGadget/TiltOverGadget.htm

I have also found it useful on WARC bands simply by using a tuner.

Well I've worked with the center fed Lazy H antenna design on 10 meters for several few weeks now. I tried 1/2 wave spacing between the top and bottom elements, 5/8th wave spacing between the top and bottom elements, I put it up at 40 feet and 50 feet at the top wire, I tried different lengths of 450 ohm feed-line, and this antenna consistently under performs a 1/2 wave dipole cut for the same frequency. A simple 1/2 wave dipole consistently out performs the center fed version of Lazy H antenna even when the Lazy H is given a 20 foot height advantage over the lowly dipole. I even put up the Lazy H in two completely different locations over 180 miles apart. I also tried two completely different antenna tuners (Dentron MT-3000a and Drake MN-75 with the 4:1 balun installed). Out of over 200 A/B test the Lazy H antenna only out performed the dipole on one test with a station in Texas just before the propagation faded out for the day, The next day when the propagation was back I heard the same station on the same frequency and the dipole out performed the Lazy H for the rest of the day.   I'm not sure what special propagation mode is required for the Lazy H to have some gain through some pin hole direction, but the version of the Lazy H center fed with 450 ohm ladder line back to the antenna tuner is a complete failure. I even re-built the antenna from scratch using a different piece 450 ladder line for the inter connecting piece. I also verified the length of each 1/2 wave section with a tape measure. I verified with an ohm meter that the top left element was connected to the bottom left element and the right top element was connected to the bottom right element. I verified there was no unexpected connectivity between the left and right elements, and I verified both sides of the ladder line were connected back to the antenna tuner. I made sure there was no twist in the ladder line connecting the top and bottom elements.

I would like to petition the ARRL to remove the center fed Lazy H from the antenna handbook as it clearly does not work as specified. A lowly mono band dipole on the same design frequency will consistently out perform the center feed Lazy H even when the Lazy H is given a 20 foot height advantage on10 meters.

Before any of you reply with charts and graphs from EZNEC software, turn off your computer, go out in the back yard, and actually build a center fed Lazy H antenna with 450 ladder line all the way back to the antenna tuner. Then do real world A/B comparisons with a plain old mono band dipole cut for the same frequency, and you will find I am telling the truth. The center fed Lazy H does not have any gain over a 1/2 wave dipole broadside to the antenna. None.

Here is what you will fine if you actually build the center fed Lazy H and compare it to a 1/2 wave mono band dipole cut for the same same frequency;

1) Your tuner will have to use extreme setting to match the Lazy H.
2) In some instances the tuner will not be able to match the Lazy H depending on the length of the ladder line feeding the antenna. You may have to increase or decrease the length of the ladder line feeding the Lazy H to get your antenna tuner to match it.
3) A 1/2 wave dipole will beat the Lazy H 99.99 percent of the time in it's favored direction even if the Lazy H is given a 20 foot height advantage over the dipole.
4) An extended double zepp with a 450 ohm matching section back to a 1:1 balun and then to 50 ohm coax cut for the same frequency and hung from the same ropes previously used to support the Lazy H will blow the Lazy H in the dirt.

In a nutshell, this antenna sucks!

Michael Rawls

Hi Michael,

I'm sorry to hear you think the lazy-H sucks. I used one on 20m years
ago and it worked just fine--and no trouble in matching it with a
tuner.

However, I have a suggestion: Let's say you space the upper and lower
radiating elements by 180=B0, which is 1/2wl. If you now use 450-ohm
window line, the velocity factor for the line attaching the two
elements together makes the electrical length of the line greater than
1/2wl, which means the phasing between the upper and lower elements is

no longer correct, and therefore will not provide the expected gain. I'm not sure how much phasing error that will produce, but it's an issue you should consider. Correctly constructed, the lazy-H will definitely out perform a 1/2wl dipole, so if it doesn't for you there is sum ting definitely wong!

If you feed at the center of the line connecting the two radiating elements the phasing will be correct regardless of the velocity factor, because the length from the center feed point on the connecting line will be the same from that point to each radiating element. With this configuration of feeding don't put a twist in the connecting line--the two radiating elements MUST be fed IN PHASE! If they're fed out of phase the array will look like an Adcock direction-finding antenna, with a deep null in the radiation pattern in the broadside direction.

Just my thoughts,

Walt, W2DU

Not many, certainly... but I would offer that those who do are able to enjoy the hobby more thoroughly than those who don't. Whether or not that additional enjoyment makes up for the extra time needed for learning, well, that's up to each individuals.

I personally care about these things, and even for hams who think they don't... most all of them have probably thoughts to themselves, at one point or another, "Hey, what happens if you feed a dipole off-center?," and it's nice that someone else has already gone through the effort to figure it out such that the answers are readily Google-able! :-)

Thanks for your input Walt, but I already thought of those things. I definitely made the antenna correctly. According to the ARRL handbook when center feeding the Lazy H increasing the spacing beyond 1/2 wave makes the gain go up until the spacing reaches 5/8ths wave. The handbooks states 5.9 dbd gain for 1/2 wave spacing and 6.7 dbd for 5/8ths wave spacing. In the real world this antenna does not have any gain over a 1/2 wave dipole when center fed with 450 ohm ladder line all the way back to the tuner. The phasing was correct. On 14 MHz where it becomes two stacked dipoles the SWR comes down and the performance goes up, but on 28 MHz it consistently lags behind a dipole. I rebuilt this antenna twice. If you actually go to the trouble of making one for 10 meters, and compare it to a real world 28 Mhz 1/2 wave dipole, the Lazy H will fall far short of the predicted gain.

I have been a ham since 1986. I wondered why I had heard so few hams using a Lazy H, and the one time I recalled hearing one the signal was weaker than the other hams using a dipole. I assumed at the time that I must have been off the side of the other ham's Lazy H, but after my real world test who knows.

I'm going to remove the center feed from the antenna this week, and rework the Lazy H for end feed with a twist, a matching stub, and 1/2 wave spacing. Hopefully the end fed version of the Lazy H will live up to it's text book gain. I'd really like to have that 6 dbd gain along with the nulls off the sides,

Michael Rawls
KS4HY

One other thought, Michael, is that if you made the lazy-H with 1/2wl
spacing for 20m and then use it on 10m, the spacing is now 1wl. I
haven't seen any figures for that spacing, but isn't it possible that
with that spacing the gain might not be what you expect? Especially if
it works properly on 20m?

Walt

Hi Walt,
   I initially made the Lazy H for 5/8th wave spacing on 10 meters.
When that did not work I reduced the spacing to 1/2 wave spacing on 10
meters.  The 4 half wave elements are 1/2 waves on 10 meters.  The
antenna design is really pretty simple. I did make some contacts with
this antenna and I received some good reports, but the dipole
consistently out performed the Lazy H,  There was one contact in
Bermuda that said the Lazy H put in a stronger signal from South
Carolina, but there was alot of fading at the time.  Even when the
Bermuda contact said the Lazy H put in the stronger signal the dipole
was receiving the stronger signal from Bermuda.

Michael

I looked at that antenna in a handbook years ago.  Could not tell from that
how it is mounted.  Do you mount the elements one over the top of the other,
or do you mount them sideways like a 2 element horizontal beam ?

Hey, Sal -

Lots of good stuff here:

http://www.vk1od.net/

Fun reading.

Cheers & 73,
John

John, I have always had great respect for VK1OD, but in the URL you presented above I must take Dave to task for asserting that Cecil's concept is suspect, simply because he didn't include attenuation in the analysis of the lines.

Correct me if I'm wrong, but seems to me that a competent engineer begins an analysis assuming lines and components are lossless. Then, if the losses are going to be significant, he factors in the effects of attenuation. If the losses are insignificant he ignores them.

In Cecil's paper he is not ignoring attenuation because he doesn't understand its significance, he is ignoring it only because in beginning the analysis it isn't significant. Cecil doesn't deserve that unfortunate treatment.

Walt

Wim, in your calculation of PA output resistance via load pull, you
state:

"...load pulling with 51.2 Ohms and 44.6 Ohms:
V_out (51.2 Ohms) =3D 71.5V, I_out =3D 1.396A
V_out (44.6 Ohms) =3D 66.5V, I_out =3D 1.491A
Delta_V =3D 5.0V, Delta_I =3D 0.095A,
Hence Rout =3D 52.6 Ohms."

The following is what I obtained through actual measurement via load
pull:

Vout (51.2 ohms =3D 76.9v, Iout =3D 1.502a
Vout (44.6 ohms) =3D 71.6v, Iout =3D 1.605a
Delta V 5.3v, Delta I =3D 0.1034a
Hence Rout =3D 51.2 ohms

Wouldn't you agree that my measurement method and procedure are pretty
well on track?

Walt

I hadn't seen that particular one, John.  While looking at it, though,
I clipped off the last of the URL to get to Owen's transmission lines
page.  Lots of recommended reading there.  I've always found Owen's
musings to be well thought out and thought-provoking.

Cheers,
Tom

I agree wholeheartedly, Tom. He used to be present here and I followed
his posts with enthusiasm. Alas, he has not posted in some time now.

I emailed him and inquired as to his well-being tonight. I hope he can
rejoin us in the future.

Cheers,
John

I do not disagree, Walt, and I do understand why Cecil chose his approach.

John

Hello Walt,

If you would read again my posting (you removed my source
description), I didn't refer to your actual measurements, but referred
to your measurement method applied to my source example (my source
example is 100Vp in series with -j50 Ohm).

I hope this makes clear the differences.

You apparently have not comprehended what I am trying to say. When one is designing a piece of equipment, whatever works, works. Please don't confuse design/analysis techniques and rule-of-thumb shortcuts with the underlying principles supporting the laws of physics. Enumerating all the design techniques in the world does not tell us anything about what is happening in reality to those photonic fields and waves that necessarily must obey the laws of physics.

Even DC impulses travel at the speed of light. Electron drift velocity is much, much slower than the speed of light. Everything EM is photonic in nature. Photons must obey the laws of physics known to exist for photons. There is simply no getting around that fact. All of the magical thinking, hand-waving, design/analysis shortcuts, and rules-of-thumb in the world are not going to change those facts of physics.

If you do not understand those physical limitations (including. the difference between the two IEEE definitions of impedance) you will never understand what is actually happening in reality inside (or outside of) an RF source. I don't know what else to say.

Hello Cecil,

When one knows the physics well, one knows what to take into account
and what to left out, just to finish the job efficiently. It seems you
don't understand that principle. Is this some lack of understanding
physics?

Do you really believe that when designing an optical detector
(completely off-topic) I don't bother about noise due to quantisation?

> If you do not understand those physical limitations (including. the

Regarding PA's and IEEE definitions, I don't get paid for my knowledge (if present?), but just for delivering what has been agreed.

You introduced photons here; I think you may also introduce thermodynamics of electrons as that may be of more importance at our frequencies. I do not violate agreed laws of physics, but only leave out higher order effects that are insignificant in my opinion.

Again, just getting the "job" done is completely irrelevant. This was
an unsuccessful quest for knowledge and understanding of the nature of
an RF source - so I will say, "73", Cecil, w5dxp.com

Here:
JOB =3D finding a satisfying answer to the thoughts laid down by
Salmonella.

Understanding the nature of an RF source, can be mastered very
efficiently without: photons, momentum, extensive transmission line
theory, Poynting vector, etc. You may visit VK1OD's website
( www.vk1od.net ) for ways how to explain things.

:-) :-) :-) And that's exactly how we get 3ns delays through foot long
75m loading coils, EM wave energy that stands perfectly still in
standing waves, and reflected waves somehow existing devoid of any
energy at all.

Beyond just understanding what parts of the physics theory are important in a particular situation, there's the more general concept of compartmentalizing things. The original question was about transmitter output impedance, and to answer that question, you really don't have to get into interminable discussions about what goes on in some arbitrary load. The only things that matter with respect to the load are the voltage, current and phase between them at the output port of the source.

A perfectly valid reason to talk about the load -- what you connect to the source output port -- is how you can configure that load to establish a variety of load conditions so that you can see how the source behaves, and from that, derive the source impedance. In fact, some months past now, Wim and I had some email exchanges about that. The emails were very valuable to me, because they got me thinking about various arrangements of the equipment I have to enable accurate measurements, and brought up points about things that go on _inside_ a typical RF power amplifier that can cause you to measure things inaccurately. For example, an ALC loop with a relatively slow response time could make you think that the amplifier output impedance is quite low if you take measurements more slowly than the response time of the ALC loop. You might even decide that it makes sense to talk about amplifier output impedance as a function of frequency offset relative to the output frequency (or some similar way to talk about the "time response" of the output impedance). It all depends on what you want to _do_ with your output impedance number once you have it, and that's something I don't recall seeing much of in this thread, nor in any of the many previous threads covering the same old ground.

Cheers,
Tom

I'm trying to locate the John Smith who signs his posts with 'js'.
Does any one know his call sign? Or perhaps his email address?

Thanks, Walt, W2DU

I have made a tutorial using flash programs that will help you understand how quadrature modulation and quadrature demodulation works. It is located here:

http://www.fourier-series.com/IQMod/index.html

I try to show you without getting bogged down in the math. The hope is that after going through the tutorial that the math will be easier to understand. (The math for this stuff can be found many places online)

```

I'm living in a wooded area and am trying to hit our club repeater reliably. It's cloudy now so I'm and getting a bit of ducting but I have a lot of trees, mostly poplars, in the direct path. I would have a line of sight if not for the trees as I'm up enough in altitude. I can cut the trees, they're mine, but finding the right ones is difficult and i don't want to waste the whole grove.

I go from keying the repeater with no intelligible signal to not being able to hit it. Today I actually have an S meter reading due to the clouds. I am currently using a J-pole and will put up a Yagi soon but wonder if NVIS would work on 2m? I have only seen references to it being applied in HF.

Wait for winter and use a beam antenna to locate the tree(s) that need to be trimmed.

If a 10 element beam won't "blast" through the trees in the summer, it should get you down to a line of 1 or two trees that need to be cut.

A more radio oriented project would be to put a 6m or 10m input on the repeater. 10m should groundwave over the trees anyway. It's easy enough to test.

10m inputs are IMHO neat, at the top of the sunspot cycle, they give your repeater worldwide input. At that point a 10m output would be good too, but for now, it's not much of a problem.

Geoff.

Hello,

The repeater antenna will probably have most of its radiation in the
horizontal plane and 145 MHz is far above the critical frequency, so
your rays will leave earth.

Did you monitor the signal for several time (also winter and rain) to
```

assess the real influence of the trees? Do you have any possibility to
move the J-pole to another place?

As you can open the repeater now and then, some 10 dB additional gain
will certainly help you to get above the FM-knee (assuming that you
can get the beam at same height as the J-pole. Nice thing is, it will
also improve reception.

With kind regards,

Wim

I can't see that NVIS has any VHF backers.

Can you exploit Google Maps, satellite view, to establish a precise line bearing from your antenna to the repeater site? If you need even more help than you get from your new yagi, then such a line bearing will help identify your "trouble trees."

I had to do it for a new FD site a few years ago. We're in San Diego and I wanted to work 2m into Los Angeles. First, I used a protractor to determine LA was X-degrees True (whatever it was) from us; next, on a close-up print of the FD site, I plotted that same line bearing from the antenna site to obvious local landmarks which we then used on the the ground for pointing the 2m beam.

This is not the only approach, but it got me what I needed.

Your yagi may fix your problem completely. Other things to consider:

* Try moving your existing antenna. Even a small movement may cure the problem as you may have cancelling reflections at times. There is almost always a "sweet spot" somewhere in the vicinity.

* Try tilting your antenna to 45 degrees and see if that helps. It might improve reception due to the random polarization of the incoming signal caused by the trees.

Note: do this on a day when the signal is either weak or non-existent. You can always apologize for kerchunking. Or, use your S-meter if you have one.

Cheers & Good Luck,
John

Addendum: If you can add even a foot or two your antenna height, it may
make a world of difference.

Cheers,
John

I live in a dense mostly redwood forest. Signals vary from full quieting to not copyable. We also have two co-channel repeaters sharing the frequency, that also vary radically in strength. I can often point my 5 element 2m beam in a totally insane direction, and improve the signal.

>being applied in HF.

I just love technical posting with no numbers. It would be helpful if you would offer a clue as to the distance you're trying to cover, what manner of impervious to RF dirt is along the line of sight, antenna at the repeater, power levels, etc. For extra credit, if you disclose these plus your exact location, the repeater's exact location, and I will contrive a Radio-Mobile path profile from you to the repeater. That should give you a clue as to what challenges you are facing.
<http://www.cplus.org/rmw/english1.html>
It will look something like this:
<http://802.11junk.com/jeffl/coverage/RST/RST-KCRA.jpg>

As for a seat-of-the-pants guess as to a solution, I don't like J-pole antennas. Actually, the antenna is fine, but the way most people build, tune, and position them, is what I find disgusting. The lack of any commercially manufactured J-pole antennas (other than the American Legion J-poles) should offer a clue. Plenty of plans:
<http://www.google.com/search?q=j-pole+antenna&hl=en&prmd=ivns&tbm=isch>
but nothing from a commercial antenna manufactory.

In my never humble opinion, if you can barely talk to the repeater with a J-pole, then a yagi will offer a substantial improvement. The problem is how much gain is going to be needed to make it reliable. My guess(tm) is that the J-pole has a gain of about 2.5dBi (opinions vary on the gain), and that you'll need about 5dB more gain to get a decent link. That means you'll need a yagi with about 7.5dBi of gain. That can be done with a 5 element 2m yagi. Obviously, more gain is better as is more altitude.

Good luck.

I beg to differ. I have about 30 years experience in dealing with propogation through a dense redwood forest (Ben Lomond CA). The trees in my area are about 120ft high. While moving the antenna around may temporarily improve the signal quality by reducing frequency selective fading, multipath, reflections, and just plain bad luck, they do not tend to remain improved. Trees grow and move around. What works well now, will probably not work well tomorrow.

I gave up on fixed antenna mounts for my rooftop verticals. (Well, I
have one mounted on a tripod, but that was before I realized what was
happening). Most of my verticals are mounted on 2x12 planks, held
down to the roof with sand bags, concrete blocks, and buckets full of
water. Every few months, I move the antennas around to see if I can
improve the signals to specific repeaters.

>* Try tilting your antenna to 45 degrees and see if that helps. It might
>improve reception due to the random polarization of the incoming signal
>caused by the trees.

I beg to differ again. Tree trunks are mostly water and do an
impressive job of simulating a slot type polarization filter at 2m and
440Mhz frequencies. Leaves and branches will pass RF fairly well, but
not tree trunks. I've played with both polarizations, circular
polarization:
<http://802.11junk.com/jeffl/circular-polarization/>
and some diversity reception. Empirically, signals are about 6dB
stronger going through the trees vertically polarized, than
horizontal. The effect continues up to at least 2.4GHz. Above that,
at 5.7GHz, the signals seem to be going through the holes between the
leaves.

I must admit that I haven't actually tried 45 degrees on 2m or 440Mhz,
but I don't think it will help much. Still, it's an easy thing to
try.

>Note: do this on a day when the signal is either weak or non-existent.
>You can always apologize for kerchunking. Or, use your S-meter if you
>have one.

Do it on a windy day, when the trees are moving around, so you can see
how much it will change.

You may be right, Jeff. But he may not have 120ft redwoods around and,
after all, this is a temporary fix until his yagi comes in.

You spent more words debunking the suggestion than admitting that you don't really know whether it could help or not. Good move. And, by the way, I have experience to the contrary at both 144 and 444 MHz. It all depends on the location of the source and the receiver. At 2 meters, some rotation of the antenna can sometimes be helpful. Note that we are not concerned with GHz.

30 years of trying to maintain a stable signal to several distant
repeaters is sufficient to convince me.   Trees move and grow, causing
signals to change.

Also, temporary is a rather useless term.  In my experience, if it
works, it's permanent.

>Good for you! Pat yourself on the back.

Thank you for the traditional contentious remark.

>You spent more words debunking the suggestion than admitting that you
>don't really know whether it could help or not.

True.  I spent more words explaining why I suspect it will not work,
what I expect will happen, and a bit of substantiation.  I consider
this a substantial improvement over the traditional one-line
pontification.

>Good move. And, by the
>way, I have experience to the contrary at both 144 and 444 MHz. It all
>depends on the location of the source and the receiver. At 2 meters,
>some rotation of the antenna can sometimes be helpful.

Perhaps it would be helpful if you read what I had written.  I said
that rotating the antenna might help temporarily, but that movements
of the trees, tree growth, swaying branches in the wind, and possibly
sources of reflections, will soon negate any temporary benefits.  If
the yagi is going to arrive shortly, then tilting the antenna is
probably a useful exercise.

> Note that we are not concerned with GHz.

Topic drift follows:
Since you mentioned GHz, one of the other problems with living in the
deep dark forest is that DBS satellite dish reception is a problem.  I
hacked an 8ft diameter hole in the tree canopy by lopping off some
```

branches at about the 80ft level, through which I point my DirecTV
dish. Every year, the trees grow a little, requiring that I move the
dish around my roof. During the twice annual solar satellite outage:
<http://en.wikipedia.org/wiki/Sun_outage>
Twice a year, I photograph the sunlight shining through the hole and
onto the dish and roof. If there are shadows of branches on the dish,
I move it to a better location.
<http://www.11junk.com/jeffl/pics/DBS/>
Note the shadow at 12 o'clock on the dish.

If you have line of sight to the repeater I find it hard to believe that
a few trees will cause you problems at 2m.

NVIS will not work at vhf it is an HF mode. 2m signals go straight
through the atmosphere they are not reflected back down.

You don't say how far away the trees are, but if they *really are* the
cause of you problems, if they are at any distance then they will
probably all have to go to give any sort of Fresnel zone clearance at 2m.

A simple map and compass will give you the bearing to the repeater, but
perhaps you would be better off running a propagation prediction program
such as Radiomobile to see if it is actually the terrain rather than the
trees that are the problem.

Ummm... I don't think the yagi is on order.
<http://www.k7jep.org/node/107>

#Begin speculation();

His area has a variety of repeaters available:
<http://www.k7jep.org/node/107>
I would guess(tm) N7JCT 145.230 on Schweitzer Mtn. Idaho.
<http://www.repeaterbook.com/beta/repeaters/details.php?ID=64&state_id=16>
Plugging the coordinates 48.367500 -116.628326 into Google Earth gives
me a view of the area. It seems to be in the middle of a ski resort,
that has been cleared of most trees and is full of trails. Plenty of
trees both up and down the slope, but not around the probable location
of the repeater. I can't identify the trees from the photo, but my
guess(tm) is Lodgepole Pine at about 60ft. The location is not at the
top of the hill and also has hills shading the view for about 270
degrees. I don't think this is going to be a foliage penetration
issue.

KML file for Google Earth:
<http://802.11junk.com/jeffl/kml/N7JCT possible location.kml>
JPG for those without Google Earth:
<http://802.11junk.com/jeffl/kml/N7JCT possible location.jpg>

Blundering forward, N6SXR is shown as getting his snail mail in
Sandpoint ID a distance of about 7 miles. However, there's quite a
bit of dirt in the way, which will be a problem.
<http://802.11junk.com/jeffl/kml/N6SXR to N6JCT.jpg>

At 7 miles, it should be possible on VHF, even with 450ft of dirt in
the way. My guess(tm) is that there's something wrong with the home
made J-pole, coax, radio, or all the aformentioned.

Again, this is a guess(tm) of both the repeater and it's location and
just might be totally wrong.

#End speculation();

The OP already said he will be putting up a yagi. Anthing he does
between now and then is temporary.

>> Good for you! Pat yourself on the back.
>
> Thank you for the traditional contentious remark.

You earned it.

>> You spent more words debunking the suggestion than admitting that you

I find it more useful to encourage experimentation rather than the opposite.

I did read what you had written. So?

>> Note that we are not concerned with GHz.
>
> Topic drift follows:
> Since you mentioned GHz,

You are the one who brought it up:

"The effect continues up to at least 2.4GHz. Above that,
at 5.7GHz, the signals seem to be going through the holes between the
leaves."

Perhaps you should read what you wrote.

John

Now you are just being argumentative. I never said it was on order. The OP said he was planning to put one up. Therefore, it will most likely come in some day.

I'll bet you are still waiting for your boat to come in.

>Now you are just being argumentative.

Not really. Methinks that you're being overly defensive. My litmus test is "duz it answer the OP's question"? If not, you're wasting your bytes. By asking for help with the design and contruction of a yagi, it appears that the author is planning to build his own yagi. I haven't seen any mention of a structure, pole, or tower, so that will also need to be constructed. Perhaps also a rotator. Methinks temporary might be a long time.

>I never said it was on order. The
>OP said he was planning to put one up. Therefore, it will most likely

At this point, I think were suppose to debate the definition of
temporary. I think I'll pass.

>I'll bet you are still waiting for your boat to come in.

Nope, no waiting. I let the computah do that for me.
<http://www.marinetraffic.com/ais/>
The station I'm slightly involved with is at:
<http://www.marinetraffic.com/ais/stationdetails.aspx?station_id=112>
Watching the VHF propagation effects are fascinating.

For this kind of thing "RadioMobile" from VE2DBE is the application of
choice. It will load the SRTM terrain DEMs, etc. and plot out the path
quite nicely.
http://www.cplus.org/rmw/english1.html

But, if you can get in sometimes, but not others, the next question is,
"can you hear it"?

How long is your coax?
If more than 20 ft, are you running a preamp?

Getting 10-15 dB gain over a jpole would be easy with a moderate length
Yagi. A M2 2M4 (4 elements, $115) is about 10dBi. A 2M9($240) is about
14dBi

Does the 40 meter addition change the 20 meter reflector beam to the center beam
and the reflector
beam to 15 meters?

I am assuming the A3S by itself works as the shortest beam is 10 meters the 15
meter beam is the
middle and the 20 meter as the longest?

TIA

Hello,

As you can see from the replies, we are in the speculation phase. If you would like to receive more specialized feedback, you should provide us with more details about the path, antenna height, nearby obstacles, vegetation in between, etc (maybe some pictures).

As we are discussing 2 m wavelength, obstacles that may be optically in the path may introduce less attenuation then expected, but obstacles that are outside the optical path can still introduce attenuation.

At 10m (33ft) from your antenna, the first Fresnel zone is about 9m (30 ft) wide. In addition, the tree attenuation at these frequencies is not that high. I think of 0.15 dB/m (I hope somebody can confirm this). It can be less due to diffraction (bending) of the waves around and over the trees.

I am almost sure, removing some poplar treetops at 10m from your antenna or more will not change the situation from marginal to good (because of the relative low attenuation).

Just to be curious, what type of poplar do you have at your site.

With kind regards,

Wim

This is the repeater I am trying to access, 146.780, K7JEP. I have been
playing with Google Earth and getting coordinates so I can go over to my
neighbors property and stand on the ridge between our properties and see
if I can see the repeater and my house. Hopefully that will help me
locate the suspect trees.

This repeater is 59 on signal. I have direct line of site with no
obstructions.

> <http://www.repeaterbook.com/beta/repeaters/details.php?ID=64&state_id=16>

The repeater, 146.780, in on Gold Mtn., 48.219713, -116.482883 I do not
know the specs of the repeater. I am at 48.494070, -116.447788, at
2300' using an American Legion J-pole. It has worked very well in the
past but this is the first time it has been up in 15 years. It hits the
145.230 repeater on Schweitzer 59. I'm running a Kenwood 721 at 25
watts trying to hit the 780 repeater. Schweitzer can be hit at 5 watts
no problem.

According to his lat/lon numbers, he is 19 miles from the repeater and
its bearing is 185 degrees (ref true north) from him. The repeater is
about 2000 feet above him (not including the tower height). He is in a
valley that has little altitude variation until his signal reaches the
mountain.

This info is available from Google Earth using his numbers.

All of this leads me to think that something else is wrong. I can hit a
repeater 20 miles from me with 5 Watts and its antenna is on a 300 ft
tower. My antenna (half wave end-fed dipole) is on a 20 ft mast.

I have tons of deciduous trees between me and the repeater but the
signal is always solid with no noise on it (I don't have an S-meter) and
I have never had a report of noise on my signal until I tried to carry
on a conversation with 200 mw output power.

Cheers,
John

I'd just put up the yagi, and likely be done
with it. That should get you over the hump well
enough to use the repeater.
You probably don't even need a rotor.
Just aim it at the bad machine, and if the
other one is as good as you say, it will likely
be usable even aimed at the other one.
Or you could use a switch to go back to the

vertical. If the coax run is long, don't use
thin coax like RG-58 or it's ilk. I consider
RG-8/213 types the minimum for anything semi
critical. And you can get better than that.
Doesn't pay to use a gain antenna if you lose
a large chunk of it in feed line losses.

Hello John,

With Google maps, results (distance and bearing) are similar (based on the data given by Kirk).

If the trees south of his antenna are the problem (I am not convinced), he needs to cut lots of them. They are about 150m from his antenna, and at that distance first Fresnel zone width is about 30m (100ft).

It seems flat when looking to the activities in the valley. I hope somebody can make a path profile and loss simulation to see what is the real obstacle.

With kind regards,

Wim

I was up on my neighbors property along the path to the repeater and the

quantity of trees is a lot more than I had remembered. Since this is
tree growing/logging country it is not feasible for me to be cutting
huge amounts of trees. The deciduous can go but there are to many
conifers on both properties to cut just for signal. You are correct on
the distance to the grove and it is the, I believe, the only impediment.

I download the Radio Mobile SW that someone suggested but am still
trying to figure out how to use it.

There may well be something wrong with the antenna. I don't have an SWR meter handy but will try and borrow one from a club member. The J-pole was beat around quite a bit over the years but since the radio has a limiting circuit if the SWR is too far out of whack I am assuming it is fairly close. It will transmit of full power. I'm using 75' of professionally assembled RG8X which is required to get from the radio to the antenna.

Not to make light, one of these poplars is tons in itself. They are easily 70' tall and 24" diameter. I truly appreciate all the help from everyone.

That's quite a drive. Thanks for the numbers. I've ignored the antenna heights as they don't seem to make much difference. 31 km (19 mile) path length. The K7JEP repeater seems to be on a wide flat part of a hilltop. Pointing downward, it may not clear the edge of the flat part if the antenna isn't high enough. Difficult to tell without photos or numbers. Not much you can do at your end to fix that. Any chance you have a photo of the K7JEP repeater antenna location?

Otherwise, the path is line-o-sight, and should be quite usable with your American Legion J-Pole. Of course, a yagi would be better, but I think tinkering with your J-pole, coax, connectors, and radio may be a better solution (assuming the repeater is working properly).

Radio-Mobile will give you the expected coverage area and signal
strengths from your location. However, it's a tricky program to
master and will require some patience and practice. There are
tutorials. For example:
<http://www.pizon.org/radio-mobile-tutorial/index.html>
<http://www.bcwireless.net/moin.cgi/RadioMobile/Tutorial>
<http://radiomobile.pe1mew.nl/>
etc.
Also check YouTube for various video tutorials.

The American Legion J-pole is rather critical, especially the dual band flavor. The vertical section of electrical wire between the coax connector and the part where it's wound around the driven element is the tuning adjustment. Move it slightly and it's mistuned. You'll need a VSWR meter to re-tune it.

>I'm using 75' of
>professionally assembled RG8X which is required to get from the radio to

RX-8x is 4.5dB loss per 100ft. Half your power is being lost in the coax.

I have heard from a club member that the repeater is weak and it has been overrun by one on the coast! He is much farther away than me and in a much less desirable location, signal wise.

I have been out of HAM radio for about 15 years so am having to relearn
quite a lot. Had a brain injury, doh!, so lot's of what I knew went bye
bye. Lot's of holes in the memory. I will find out about the repeater
during the next club meeting. Specs and all.

One of the things to know about the American Legion J-pole (and most vaguely-similar J-poles) is that it has no feedline or mount-point isolation to speak of. The outside of the feedline coax, and any pipe or tower or other metal to which you strap the antenna, become part of the antenna's ground system, and can radiate a significant amount of RF. This can interact with the RF coming from the main radiator, and significantly alter the antenna's pattern... it no longer behaves like an idealized half-wave vertical radiator.

In most installations this doesn't seem to matter all that much... but it's possible that you've got some sort of weird interaction (feedline emissions, reflections from the ground or nearby metal, etc.) which is creating a null in the antenna's pattern in just the wrong direction. If this is an issue (not all that likely but perhaps possible) you could insulate the antenna from the mounting mask, and install a choke (e.g. a few ferrite cores) on the feedline just below the antenna.

Also, the American Legion J-poles are subject to a couple of forms of mechanical/electrical failure after a few years. The plastic insulator which spaces apart the radiator and matching arm can degrade (UV from sunlight is the main offendor, I believe) and crack, allowing the two arms to change spacing. More subtly, the connection between the two arms and the metal base can degrade... it's aluminum-to-aluminum using a set-screw, and the connection can loosen and corrode.

It might be worth checking the spacer (replace if necessary), and checking and tuning up the set-screw connections (squirt with Liquid Wrench if necessary, loosen and remove, take out the rods, clean the ends of the rods and the mounting holes in the place, dab with NoAlOx or a similar corrosion-blocker, reassemble and tighten).

>   I'm using 75' of
>professionally assembled RG8X which is required to get from the radio to
>the antenna.

That's probably costing you about half of your power (assuming a typical RG8X-type coax). Some lower-loss types (e.g. LMR-240 are better than this.

I wonder whether he might have his antenna sitting in a particularly deep multipath cancellation null.

I help run a repeater located about 4 miles from my house, which is up at about 80' AGL on a hospital roof. There's an office building blocking direct line-of-sight path from my house to the repeater.

For a few weeks, several years ago, I found myself unable to successfully open up the repeater using my base station, even while transmitting 50 watts of power from a good-quality commercial 2-meter antenna located a few feet above my roofline. Had no trouble with any other repeater in the area, or with simplex operations. The feedline/antenna system measured out just fine... no reflected power worth speaking about.

I moved the antenna mast about 2' to one side, and was then able to open up the repeater full-quieting with 100 milliwatts.

All I can figure is that there must have been a *very* deep multipath cancellation effect playing out... maybe interference between a edge-diffraction path involving the office building, and reflections from nearby trees. Moving the antenna a fraction of a wavelength changed the path lengths enough to eliminate the cancellation (or reduce it by a large factor).

I sort of think also, the Lazy H (think colinear?) should be fed and phased with 75 ohm line.

On Mon, 30 May 2011 14:48:45 -0700, walt wrote:

If you feed at the center of the line connecting the two radiating elements the phasing will be correct regardless of the velocity factor, because the length from the center feed point on the connecting line will be the same from that point to each radiating element. With this configuration of feeding don't put a twist in the connecting line--the two radiating elements MUST be fed IN PHASE! If they're fed out of phase the array will look like an Adcock direction-finding antenna, with a deep null in the radiation pattern in the broadside direction.

Just my thoughts,

Walt, W2DU

People who are running NEC models, particularly NEC2 as opposed to NEC4, tend to be interested in this kind of thing.

While building antennas and running them up the flagpole/tower/tree to test is fun and enjoyable, you can save a whole bunch of time with some modeling ahead of time (and besides, sometimes the weather isn't good for antenna building/testing)

And there's a whole raft of "off center fed" dipoles of one sort or
another out there, particularly for multiband applications, so it's nice
to understand that what's really going on is that the feedpoint
impedance you see is basically the same as feeding at the center, but
run through a "transformer".

A bit of theory helps one evaluate all the "secret recipe worked 1000
countries on top band with 1 Watt and a 3 foot long antenna" stories too.

Another point to consider, Mark, is that the azimuth beam width is
narrower with the lazy-H than that of the dipole. So perhaps the
apparent lower signal level is in directions off the side of the
radiation pattern, where one would expect the signal level to be lower
than that of the dipole at the same angle.

Walt

Me, me, me. Even the simplest antenna is influenced by nearby structures, towers, poles, elevation, guy wires, position of coax feed, chain link fences, and grounding system. That makes a simple dipole not very simple. I've helped a few local hams model their houses allowing prediction of takeoff angles, mysterious nulls, optimum height, and cut length. While modeling (I use 4NEC2) does take some learning and understanding, it does offer an improvment over the tradition ham radio cut-n-try.

>Too much hand-waving here to be useful to most folks.

Speak for yourself please. I like postings that are over my knowledge level so that I learn something new. It's also nice to know *WHY* things work, or don't. Learn by Destroying(tm).

Or another way to think about it (perhaps closer to what's going on)
is that it's like changing the position of a tap on a resonant tank
circuit.  If you get into building RF filters using coupled
resonators, you'll appreciate that changing the tap position on the
input and output resonators changes the filter's operating impedance,
as seen at the input and output, though just as in the off-center fed
antenna, the current distribution in the resonator (or antenna)
changes relatively little.  For the case of the antenna, of course,
you have to decouple the transmission line very carefully if you feed
it off-center -- or else just allow for the fact that there _will_ be
antenna currents on the transmission line e.g. an end-fed half-wave).

I agree, Jeff.

I like antennas that are naturally short-circuited by design and can be grounded, making the feed point essentially grounded for DC and lower frequencies. One such antenna is the folded unipole. Its only problem is that the feedpoint resistance is about 120 or so ohms.

So, I had this idea. The usual monopole (or ground plane) has about 30-35 ohms resistance. To get 50 ohms it is common practice to droop the radials about 45 degrees. Since that raises the feedpoint resistance, would raising the radials lower the feedpoint resistance of the folded unipole and, if so, what effect would it have on the pattern?

EZNEC said to raise the radials of the folded unipole about 23 or so degrees to get 50 ohms and the pattern would not be affected.

So I built one and it works swimmingly. I had to make some minor adjustments in element lengths but that was fairly easy with the vector voltmeter. Hooray for modeling.

Cheers,
John - KD5YI

Hooray also for using your head, John, and realizing that raising the radials would _probably_ have that effect -- then having that verified by a model, and then by an antenna that works well for you in practice.

Another way that should work: make the two parallel conductors different diameters, with the correct spacing. You might also try making a self-supporting grounded quarter wave, resonant with its radials, and fed with a parallel conductor that doesn't go all the way to the top of the quarter wave...

So there are three different arrangements, perhaps with pretty similar electrical characteristics, and you can then pick among them for the one that suits your construction practices the best. Perhaps there are some more "grounded" monopole designs you throw into the mix.

Yes, if you're "just throwing up a dipole," maybe you don't worry about things like this, but there are those of us who like to think a bit deeper about things. I can only hope I remain infinitely tolerant of those who like to think much deeper than I about many things.

Cheers,
Tom

Slick... and I bet that the appearance of it raises the occasional question and/or eyebrow!

The matching approach I've usually seen for folded monopoles, is to use a quarter-wave transformer made out of (e.g.) RG-6 or another 75-ohm coax... this brings the impedance down to something not too far from 50 ohms. Your method avoids the need for this.

If I were to build one I think I'd stick a fat cap over the end of each raised radial... just to reassure myself that I wasn't setting up an "automated pigeon-skewering device" of sorts :-)

I use it at home. Nobody in the area knows enough to even blink an eye.

> The matching approach I've usually seen for folded monopoles, is to use a quarter-wave transformer made out of (e.g.) RG-6 or another 75-ohm coax... this brings the impedance down to something not too far from 50 ohms. Your method avoids the need for this.

I am aware of that method. I think the challenge for me was to have it
all inherent.

As a matter of fact, I can see where just jumping into it without the
benefit of modeling would probably have resulted in giving up on it. I
had to adjust many things (such as radial tilt) before I learned about
how things were going to be affected. Modeling is like having an antenna
breadboard but a whole lot less work.

> Another way that should work: make the two parallel conductors different diameters, with the correct spacing. You might also try making a self-supporting grounded quarter wave, resonant with its radials, and fed with a parallel conductor that doesn't go all the way to the top of the quarter wave...

I looked at those (EZNEC) years a go and was never satisfied. I have learned much more now, so I might benefit from another look.

>
> Cheers,
> Tom

C'mon, Tom. You're a very knowledgeable person and I value your input. That's plenty deep.

By the way, I used Walt's inherent balun to make a diamond-shaped antenna which needs no additional balun. It is 50 ohms at the feedpoint. It, too is inherently short-circuited and, with the inherent balun, probably groundable.

It was an interesting exercise that went like this:

1. I like a loop for the inherent short-circuit.
2. It has about 100-120 ohms terminal resistance. I want 50 ohms.
3. It needs a balun. But, I don't really want one.

A folded dipole is about 300 ohms. A half-wave shorted transmission line is about 0 ohms. So, if you take a shorted half-wave transmission line and spread the wires apart at the 1/4W point all the way to where it becomes a folded dipole, it seems to me that the terminal resistance will go from zero to 300 ohms and 50 ohms is in there somewhere.

I tried it in EZNEC and found that to be the case. I found that, if the acute angle of the rhombus is about 51.5 degrees, then the terminal resistance is about 50 ohms (adjust perimeter along with angle to get 50+j0).

Ok, fine. That takes care of everything but the balun. In Walt's Reflections III, he discusses the half-turn bifilar loop (page 22-10). But what was intriguing was the inherent balun. Aha!

So, after modeling as well as I knew how, I constructed a rhombus (diamond-shaped) antenna with the right half of the diamond being coax (inherent balun) and the left half of the diamond being 14 ga wire.

The velocity factor of the coax means that its electrical length is about .6 of a half wave (or .3 lambda) where I wanted 1/4W, but it is close enough. I have not been able to measure current on the outside of the coax, but it may be because I have not yet created a sufficiently sensitive probing method.

I've not yet installed it. Maybe in the next few months I can get to it.

Cheers,
John - KD5YI

As an aside, I found it time consuming to adjust angles and repeat the source impedance test in EZNEC. So, I created an Excel spreadsheet where I could simply input the perimeter, the acute angle, height above ground, wire gauges, and number of segments and wrote a short VBA to gather the spreadsheet results and create an EZNEC importable file.

Man, what a time saver.

73,
John

Are you feeding this with coax? Why not use a big choke at the feedpoint on the outside of the coax (i.e. a bunch of suitable ferrite toroids)?

It's not like antenna itself cares which side is connected to shield or center conductor (as long as no current is being carried on the outside of the shield?)

It should work basically identically as a scheme with a coax balun, so you could choose which ever is mechanically or cost-wise more convenient. (I happen to have a box full of 31 mix toroids for such things, you might happen to have extra coax or a clever way to support it..)

I don't understand. The built-in inherent balun needs no choke.

John

No. The left-hand side is #14 wire while the right-hand side is coax (obviously left and right can be reversed). A BNC female is at the bottom, bayonets downward, terminals upward.

```
                 o
                / \
               /   \
              /     \
             /       \
            +         +
             \         /
              \       /
               \     /
                \   /
                 oo
```

The coax (right side) is connected as usual to the BNC and bent as shown. However, the coax's center conductor *only* is connected at the top to the #14 wire on the left of the diamond. The bottom end of the #14 wire is connected to the BNC connector shell at the bottom.

The piece of coax on the right forms the balun. It is close to 1/4W internally considering the velocity factor of the coax, but about 1/2W externally.

As I said, it isn't exact. It measures very well here. I measured VSWR of 1.02 but that was not the important part of all this. I have yet to measure current on the transmission line from the BNC to the source to my satisfaction.

If I can supply clarifying info, let me know.

73,
John

I meant to give Walt (W2DU and Reflections III) credit for the inherent
balun as before. My only contribution is my discovery (or re-discovery)
that the terminal impedance of the antenna can be adjusted within the
limits mentioned in my earlier post.

One other post script: As the quad departs from a square, it seems that
the antenna gets a bit more touchy with regards to dimensions. It is
difficult to tell for sure, though, since I'm doing this at 434 MHz and
everything is touchy there.

Cheers,
John

I "MAY" have figured out what was wrong with the Lazy H. This is a tentative post.

The Lazy H is located in Charleston, South Carolina and it is broadside to Southern California. It should be aiming just barley north of West and just barely south of East. The first clue came when a station in the Caribbean gave me a 20 over S9 report. That direction should be in a null spot. The propagation has been coming in from Texas, Southern California, Central and South America, and the

Northeast (New York, Mass, New Jersey, etc). Well today the propagation rolled in from the North west, and I saw a signal increase from a station in Iowa when I compared the Lazy H to the dipole. That is not the direction the Lazy H is facing, so it occurred to me there might be something skewing the propagation angle of the antenna to the north west and south east. Since there has not been any propagation from the North/west direction until today I had nothing to test it against. I went outside and noticed the 450 ohm feed line was not coming away from the Lazy H at a 90 degree angle. It was more of a 45 degree angle. I added some length to the 450 ohm ladder line, and then repositioned the feed line to come away from the Lazy H at a 90 degree angle. When I went back to test the antenna it was beginning to show gain in the intended direction. Also the tuner had an easier time matching the antenna. I may have to play with it some more, but I may have found the missing 5.9 dbd gain with 1/2 wave spacing. I'm going to keep my fingers crossed and hope I don't have to retract this post.

That sounds like something that would be valuable to others, too,
John.  You might think about making it available...

BTW, I do think pretty deeply about a lot of things, but there are far
more I don't bother with.  Still, people who do think deeply about all
those other things hold my respect for what they do, whether it's
topics I have any interest in or not.  Along with that is an
understanding of how important it is that we can freely share what we
learn with others.

Cheers,
Tom

Changes followed by "|".

After a 30-day public discussion and feedback period to gauge reader opinions in March of 2009:

http://groups.google.com/group/rec.radio.amateur.moderated/browse_thread/thread/d7d337db35f23326

the rec.radio.amateur.moderated Moderation Team has decided to consider amending its charter, and permit limited simultaneous crossposting to rec.radio.amateur.moderated and one other unmoderated amateur-radio-related discussion newsgroup. We are currently trying this on a temporary basis (90 days, through early July 2009), and adopt it permanently if successful.

Approved rec.radio.amateur.* newsgroups are those that are currently listed in the latest version of the "List of Big Eight Newsgroups" which is crossposted monthly to news.announce.newgroups, news.groups, and news.lists.misc.

Approved alt.radio.amateur.* and alt.ham-radio.* newsgroups are those that have been created consistent with the suggestions in "So You Want to Create an Alt Newsgroup" at:

  http://www.faqs.org/faqs/alt-creation-guide/

Approved regional hierarchy newsgroups are those that contain either "radio.amateur" or "ham-radio" in their names, including uk.radio.amateur and aus.radio.amateur.misc.

We will make every reasonable effort to keep our list of approved newsgroups up-to-date. In case we have overlooked any, and a submission is rejected in error as a result, the rejected submitter can E-mail us at our administrative contact address (in the signature at the bottom of this article, and the default Reply-To for the rejection message) requesting that it be added, and that the article be approved. We may still choose to reject articles crossposted to any alt.* newsgroup with an inappropriate name, including obscene language, embedded name-calling, or encouragement of unlawful conduct.

Please direct any comments, questions, or criticisms to rec-radio-amateur-moderated-request@panix.com.

It is so narrowly focused on the rhombus that I doubt it would be useful
to anybody else. But, it is available to anybody who wants it.

John

I am still working on finding where the problem is. I pulled the J-pole
down and checked the resistance of the separate connections. I didn't

want to pull it apart if not necessary. Everything showed 0.0 to 0.1 ohms. Seems fine to me. I then cleaned the connector as throughly as possible using emory cloth inside and dremeled the outside with a fine wire brush. There was a small amount of oxidation and it appeared much cleaner and brighter after. I also straightened the two elements but they were not really that bent. You had to look down the long axis to see any deviation. They are as straight as they are going to get but I can't believe that would make much difference.

After all this I put it back up to it's original height. There was not discernible change. I was almost unreadable at the repeater.

Next I pushed up my mast a few feet more. It is a 50' pushup that normally requires guy wires. I am not using any so I am leaving considerable overlap of the sections. I would estimate it is up around 32'. Even in high winds here I saw little deflection with just the J-pole. The 3 or 4 feet I pushed it up gave me a little bit of improvement. When I win the lottery I'll get a 100' tower put up. Guess I'm stuck with this then :-)

I still think it is the trees and have taken a picture from the roof peak towards the repeater so you can see what I am dealing with.

http://www.ncc-1701a.net/Ham Radio/ForestObstruction.jpg

It is deceiving as there are many more trees behind this line on my neighbors property. I wouldn't even think of asking him to cut any. They are money in the bank for him.

Hi, Kirk -

It looks more formidable than I had imagined. I am sure the picture will
generate some comments.

Nobody can say you aren't making maximum effort, for sure.

When will be that club meeting?

73,
John - KD5YI

Kirk -

Do you have parts on hand such as extra coax, connectors, wire, etc?

Although you have done a thorough job of examining your installation, it
behoove you to make a test separate from your present antenna installation.

For example, you could simply strip 1/4WL from the end of a coax feeder
and put that end on the roof temporarily. I know, not the best match,
common mode currents down the line, signal launches upward, etc. But, it
is simple and might tell you something.

Maybe a quick, thrown-together ground plane?

Just a thought.

73,
John

I don't think anybody asked you:

How much power are you putting out?

How well do you hear the repeater; are there times when it fades below squelch while you're listening to other people?

(No, I don't have a 2m PA that I'm trying to unload.)

Sal

Sal,

My TM-721A is putting out 35 watts. At least that is the spec. The repeater is always scratchy and barely readable. I've only had one time when it even showed up on the S meter. That was low clouds so I assume it was cloud bounce.

I hope I don't sound to ignorant here, too often thats the

case.
But If you have a known working Wifi AP with a high end
reputation like Cisco Airnet model 2400 for instance.
They advertize 1 watt, it's one watt no funny bones about it
or busnesses wouldn't respect their higher prices and pop for
it.
 Take an EMF meter like the one on Ghost Hunters TV show,
radio shack has them, and set it ten feet LOS from the AP
[Cisco] wile downloading a big video file or something large,
and set that as your "One Watt" point, now you have a
comparason, of course notice the Antenna "Type" and location.
Heck you can use a cheap NetBook with built in WiFi and
NetStumbler software to measure the IF strenth. All you have
to be sure of is the output of your "Sample" source.
My Alfa USB WiFi unit LIES!!! they claim a half a watt, NO
WAY!!! I bet if Cisco built it they wouldn't lie about that
stuff, and of course it would cost more than 60 bucks.

If the unit has high dollar choices of hard ware use a DRAC 5 net card, our Dell servers use them, When you Telnet into them and command a shutdown, it does not argue, it shuts down even at the cost of head crash!!!!   DRAC 5 is a robotic remote control to the backend of whatever unit you are using it on. It's like pulling the plug out of the wall, game over, the unit automatically Restarts unless you send a shutdown - stay down command. DRAC 5 cards are just as cheap as NIC cards and install the same way. See if the WiFi transmitter had a DRAC 5 option when buying, Our high end cysco stuff comes with them.

Hello Kirk,

If you have access to both ends of the cable and have access to some
VSWR measurement equipment, you may measure following things (and post
them overhere):

VSWR of cable when terminated with a dummy load
VSWR of cable when open
VSWR of cable when short-circuited
VSWR of cable with J-pole antenna

Now reduce the output power of your transceiver to avoid damage
```

VSWR when nothing connected to the output of the VSWR meter
VSWR when output of VSWR meter is shorted.

Make sure to check the reference (forward) reading after every change in load, as this may change due to varying load as seen by the transceiver. You may also do these measurements with the antenna analyser (preferably both antenna analyser and VSWR meter).

Regarding the trees, it looks dense. Sadly to mention, if it are the trees, you have to live with this as tree attenuation at 2m is relatively low and first fresnel zone is relatively large at > 160m. You need to remove lots of them to get remarkable improvement and you mentioned that you couldn't remove lots of them because of financial reasons.

With kind regards,

Wim
PA3DJS
www.tetech.nl
Don't forget to instruct your racing pigeon to remove abc before letting him cross the Ocean.

SNIP2SAVE-------
It's about 600 bucks but a Cysco 2400 WiFi with PoE support
would do this, however , remoting into a router everytime you
want to scour the bands or make an AP change is a bit of a
nucense. Thats what turns people to USB Dish and Dongle
setups. You can switch AP access on the fly, with the router
you have to "Go To Work" sort of speek. It does however
benefiet your telnet skills. :-)
If I could find a lower end name "Repeater" capable AP point
unit like a NetGear or similar and program it to autologon to
unprotected WiFi access points That would Kick butt.
Thats called promiscuous mode but has moral issues.
And another turn off, Two transmitters equalls double the
Packet overhead witch converts to half the speed even if you
have a strong signal. The KISS methoud always wins for
performance in WiFi.

There are two issues that I am ignorant to;
1; is the WEB services that are built into these routers in
order to program them too often is DIS-Allowed through the
AIR.
Most make you connect to a "DMZ" drop [cat5] on the router to
bypass the NAT firewall and administer the stats that way.
I have never succeeded in getting to that page through Wi-Fi
methods. Some routers are easy to get to through the NAT drops
provided on the router there are generally 2 or 3 of them. You
can NULL cat5 into the things direct from a laptop, but AirNet
into them? I haven't seen that [yet].

I'm looking into mounting a vertical (20 meters and higher freq) on a new patio cover.   The cover is made out of 6 inch by 16 foot aluminum channels that interlock edge to edge across a 20 foot width. Each section is powder coated (aka...."painted"), so the sections are most likely not well connected electrically to each other.

I'm considering a 10 foot long H shaped metal structure lying on the cover, with the antenna mounted in the center of the H. Radials are a possible but not desired approach. Any other suggested methods of mounting the antenna/etc.?

Uhh.. with the test scheme you describe, there's a ton of things that could be perturbing your results: mostly because you're measuring radiated power in a single direction, which is connected to RF transmit power, but also affected (greatly) by the antenna.

Different Wi-Fi implementations may have the same RF transmitter power, but have different transmit duty cycles. Your meter is doing some sort of time averaging.

The antenna performance on your two units under test is probably radically different. The little USB pods often have a small antenna which has lower efficiency.

I doubt your inexpensive meter has uniform response in all directions and all polarizations.

You could start to compensate for a lot of the latter by making multiple measurements at different positions separated by, say, 5cm (2") moving the meter by, say, 2 or 3 feet vertically, and 2 or 3 feet horizontally.

Anyway, measuring transmit power in the far field with an meter with unknown spatial and polarization response is trickier than it seems.

In addition to that, I think the emission is frequency-hopping and may
have a duty factor associated with the scheme. I think he may need a
peak-power capture scheme.

Also, how is a field strength meter calibrated for emitted power with
all the variables involved?

Just a quick update. I am seeing some gain with the Lazy H now that
the feed line exiting the antenna has been moved to a 90 degree angle,
but I don't think I am seeing the 5.9 dbd gain promised in the ARRL
Antenna Handbook. I would guess it is more around 3 or 4 dbd gain
with 1/2 wave length elements and 1/2 wave spacing between the top and
bottom elements. It seems like alot of trouble to go to when an

extended double zepp at the same height as top wire of the Lazy H might do just as well if not better. The plus is the Lazy H may have cleaner nulls off the sides which is helping with the occasional AM carriers that are coming out of Central and South America.

Michael

I'll bet they're better connected than you think. Are there sheet metal screws joining them? what's holding the strips to the frame? Can you put a wire/foil tape under the screws. In any case, it would be easy to bond the panels together with some short jumpers. I can think of a variety of ways to do this, but one of the easiest might be a strip of copper foil tape along the 20 foot length. Sand the powder coat away on a spot on each "strip", run a stainless sheet metal screw through the copper foil or braid and the aluminum. Then glop on something to seal it so it doesn't corrode or leak. Butyl roof mastic might be a good thing.

A fancier way would be to get another aluminum strip and spot weld it.

You need to seriously think about bonding the roof anyway, so that is your best bet.

But, capacitively coupling from something lying on the surface would also probably work fairly well. Wide aluminum flashing laid out from your antenna base across the top of your corrugations (bend it to fit the ridges) and glued down might work pretty well.

If you had, say, 1 foot wide by 10 feet long, and it's 1/8" max distance, that's like a capacitor of about 500pF. Put a couple or three of those strips and you're doing pretty well. For your frequencies, it's like it's actually physically connected.

It isn't..

The field strength meter measures power density (W/sq meter) or field (V/m), and you have to figure out how that relates back to transmitted power.

The OP wasn't actually reading it in power, he was using the meter as a sort of transfer standard. i.e. say it reads linearly in relative power from 0-100. You put a known 1 W source at 10 feet, and it reads, say, 88.

You put your unknown at 10 feet, and it reads, say, 44, so you calculate that the source must have been 1/2 Watt.

The problem is that you're really making more of an ERP (Tx power + antenna effects) measurement assuming an isotropic source/meter, which can easily have 10 dB of error from a variety of factors.

That makes sense. But, what about reflections, exact positioning, etc?
```

For example, in a low-signal location, moving my cell phone a fraction of an inch can change the signal from "no connection" to two bars. In a room with light fixtures, power wiring in the walls, picture frames, computers, etc, I doubt the reading can be of much value. It might be better to move the detector all around while recording readings to get an average.

But, you know all that.

I tried to cancel my last post but it may not have done so.

In thinking more about it, I have to agree. Especially in light of your
allowance of the 10 dB.

So, in summary, excellent reply.

73,
John

> Urrrrgh

That's due to an FCC requirement. The FCC says (or used to say) that the antennas on consumer-type Part 15 wireless gear had to be "not commonly available" or words to that effect. Reverse-polarity gendering, reversed threads, etc. are all common techniques... and of course, as soon as one is used, it rapidly becomes so popular that it ceases to be "not commonly available" :-)

The specific intent was to try to discourage consumers from changing the antennas on WiFi gear. The certification of WiFi equipment is done on the system as a whole (radio + antenna), and changing to a higher-gain antenna automatically invalidates the certification and makes the WiFi system technically illegal to operate (at least, until it's re-tested and re-certificated with the new antenna).

If I recall correctly, the FCC modified the rules a year or two ago. A system's manufacturer is now allowed to test their system with one or more types of antennas, having different amounts of gain, and publish the gain number for the highest-gain antenna with which the system has been successfully certificated. It's then legal for an installer to substitute a different antenna than the original... as long as the substituted antenna has the same, or lower gain than the highest-gain antenna that the manufacturer has certificated.

These rules are, I suspect, honored far more in the breach than in the observance... and there seem to be very few manufacturers who go to the trouble of publicizing the "highest-gain antenna allowed with this system" information. That's probably going to be done only for high-grade commercial gear, not consumer-grade routers or the like.

Yes, there are various connections with sheet metal strips running across
all the channels, and a self tapping screw into each channel. There are
connections between everything, but a little uncertain as to the quality of
the connections.

Just curious, how are you measuring this -2 to -3 dB difference you are
referencing?

And even the cheapest units on the market have MIMO. 59USD is the cheapest I have seen, but they could be cheaper.

For those that have never heard of MIMO it's a way of encoding more information on the same frequency by having multiple antennas spatially separated on 1 or both ends.

The upshot here is that once the unit has multiple antennas it not only can spatially encode it, it can also beam it.

Walt, you continue to amaze me with your apparently wonderful and extensive knowledge
with antennas and transmission lines. I look forward to finding threads where you have
entered a discussion on some topic or other. I have been a Ham since 1958. I've studied,
and read lots on the subject and always wished, but was never able to really understand the
aforementioned topics to any degree. I've built and played around with many antennas over the years.
Reading this newsgroup and many of the discussions has taught me a lot, but your ability to relate various
aspects which might to me be seemingly unrelated, and put them into words which are both meaningful
and understandable blows my mind. Your replies advising Michael on just this thread alone have been
great.

I've been meaning to say this for years -- now here it is --
Thanks for being around and sharing your goodies with us all.

Irv
VE6BP

One other thought, Michael, is that if you made the lazy-H with 1/2wl
spacing for 20m and then use it on 10m, the spacing is now 1wl. I
haven't seen any figures for that spacing, but isn't it possible that
with that spacing the gain might not be what you expect? Especially if
it works properly on 20m?

Walt

Hello, and moral issues aside for the moment, you'll probably discover very quickly that unlike a few years ago most, if not all, Wi-Fi access points/cable routers in your area these days are probably protected either by WEP (old) or WPA-2. (A Wi-Fi laptop with a network scan utility will usually indicate protected/open networks). And even many of those with older equipment have gotten wise.

The newer boxes usually have the protection turned on out-of-the-box with a password (changeable by the user/administrator). Older boxes had WEP turned off by default and a lot of users just plugged them in and never bothered to read the user guide and/or turn on the protection.
Sincerely, and 73s from N4GGO,

Hello, and I forgot to add that if your objective is to access public
Wi-Fi (which is usually unprotected) at a distance then have at it.
Sort of like stationary war driving. My previous comments pertained to
accessing private/home Wi-Fi nets. Sincerely,

--

Hello Walt,

It is not that I don't see the importance of reflections / wave
interference, as I use transmission line theory on an almost weekly
basis. However one don't need to complicate the matter by using
transmission line theory for a HF PA.

When you open your rig, you will very likely not find a >10" long 100uh inductor in the output section of your PA. Also your capacitors have very small size w.r.t. wavelength. A lumped circuit model and a load specified as an impedance is therefore more than good enough to discuss PA complex output impedance and what CAN happen when you apply mismatch.

You can't tell what happens exactly, because then you need to dive into the circuit diagram of the PA to evaluate current and voltage waveforms at the active device.

With kind regards,

Wim

Hello all
I just picked up an old CDE AR22R rotor and controller
It is missing the choke for the pulse switch from the rotor to the controller
anybody ever have to replace one of these or know the value ??
In the drawing it is labeled CH and part #A52 50426-00
and I cant find anything on it

Thanks in advance to all that read and reply

Hi and thanks for the info
well I emailed hygain/MFJ
Last time I emailed them about something else I never got a reply
So I don't have to much faith in this email
Will keep you posted
Howard

I can only quote Einstein (once again) for you:
"Everything should be made as simple as possible, but not simpler."

You have ignored Einstein's advice and "uncomplicated the matter" to the point of violating the laws of physics. When you use the distributed network model for part of the circuit and then switch, mid-stream, to the lumped circuit model, you are indeed violating the laws of physics (as I have pointed out to you before). But you are certainly free to delude yourself into ignoring reality and choosing to commit technical suicide in the process. When you switch to the lumped circuit model, you are presuming faster than light speeds and completely ignoring the existence of EM waves. The fact that an EM/RF signal cannot travel even one inch in zero time simply cannot be ignored. If you take that one inch speed of light delay into account, hopefully you will realize just how technically confused you really are about the magical reversal of cause and effect concepts that you are promoting.

For what it's worth, in my work I design a lot of filters and matching networks. I regularly model the designs before I build them, using the level of detail I feel is appropriate. When I build the physical filter or network I've modeled, I compare the measured response with the response predicted by my model. I do that in some detail. I almost always modify the model as necessary, adding detail so it matches the measured performance. When I say I add detail, I don't mean that I do it haphazardly, but rather that I look closely at the physical realization and add pieces to the model that match pieces of the physical realization. Because I've gone through this design cycle many times, with many different topologies and for a variety of frequency ranges from below 1MHz to above 1GHz, I have a pretty good idea before I start a new design just what level of detail I'll need.

What I find from this is that, just as Wim says about PA matching networks, I seldom need anything beyond representations of the lumped components when I'm dealing with low frequency filters that don't have high loaded-Q resonators. Up to 30MHz, I don't recall ever having to use transmission lines in my models to get excellent agreement between the model and the physical implementation (except in the rare cases where I've included transmission lines in the physical implementation of a low frequency network, of course). I do often have to add parasitic elements--sometimes even for relatively low frequency filters. (I remember having a technician build a 1MHz filter for me; he couldn't understand why his didn't work anywhere near as well as the first one I had built, until I showed him where he'd allowed other parasitics to creep in--short lengths of wire with currents shared between two high-Q resonators...) I'm _FAR_ more likely to need to include mutual inductance between two coils in a model, than I am to need to include a transmission line.

On the other hand, when I'm dealing with filters above 100MHz, it's not unusual to include transmission line sections and stubs in my models. Above 200MHz or so, the models generally do benefit from including transmission lines. Mind you, there aren't any hard and fast rules; there is no magic transition frequency. But when you've built models that match reality as closely as I commonly do, you learn to just smile blandly at those who tell you that you "must" consider a coil to be a transmission line or you'll be "wrong."

Finally, even when I do include transmission lines in my models, I don't worry in detail about reflections, or about a time-domain analysis of the situation. Just as there's an equivalence between time-domain waveforms and spectral analysis, a frequency sweep of a system (including phase as well as amplitude response) tells me everything I need to know, in the domain I'm already interested in.

I hope Wim (and others?) will excuse the off-topic drift here. And I'm _still_ trying to figure out _why_ anyone would care about the output impedance of a PA of the sort used at HF to drive antennas. Nobody has ever convinced me that it matters at all, except perhaps as academic interest.

Cheers,
Tom

Nobody is questioning the efficacy of design methods. Whatever works, works. What we are discussing is indeed only of academic interest. Knowing whether my IC-706 is conjugately matched or not does not affect its operation at all.

From the time (t0) that a PA first outputs a Zg signal to the time (t1) that the PA senses its load impedance is NOT zero time. How does the PA know what its load impedance really is when it is not Zg? Einstein's spooky action at a distance? No, feedback from the load.

Obviously, the PA receives some sort of feedback in real time. What is the nature of that feedback? What can it be besides feedback energy reflected from the load? (not in zero time, but at the speed of light). In the real world, it takes measurable time for the forward energy to reach the load and measurable time for the reflected feedback (if any) to arrive back at the PA. The load seen at the PA source is always an E/I ratio, i.e. a lossless image impedance that always experiences a delay if it is not equal to Zg, i.e. it usually contains reflected energy.

>
> What I find from this is that, just as Wim says about PA matching networks, I seldom need anything beyond representations of the lumped components when I'm dealing with low frequency filters that don't have high loaded-Q resonators. =A0Up to 30MHz, I don't recall ever having to use transmission lines in my models to get excellent agreement between the model and the physical implementation (except in the rare cases where I've included transmission lines in the physical implementation of a low frequency network, of course). =A0I do often have to add parasitic elements--sometimes even for relatively low frequency filters. =A0(I remember having a technician build a 1MHz filter for me; he couldn't understand why his didn't work anywhere near as well as the first one I had built, until I showed him where he'd allowed other parasitics to creep in--short lengths of wire with currents shared between two high-Q resonators...) =A0I'm _FAR_ more likely to need to include mutual inductance between two coils in a model, than I am to need to include a transmission line.
>
> On the other hand, when I'm dealing with filters above 100MHz, it's not unusual to include transmission line sections and stubs in my models. =A0Above 200MHz or so, the models generally do benefit from including transmission lines. =A0Mind you, there aren't any hard and fast rules; there is no magic transition frequency. =A0But when you've built models that match reality as closely as I commonly do, you learn to just smile blandly at those who tell you that you "must" consider a coil to be a transmission line or you'll be "wrong."
>
> Finally, even when I do include transmission lines in my models, I don't worry in detail about reflections, or about a time-domain analysis of the situation. =A0Just as there's an equivalence between time-domain waveforms and spectral analysis, a frequency sweep of a system (including phase as well as amplitude response) tells me everything I need to know, in the domain I'm already interested in.

Hello Tom,

Applying Cecil's rules, you and I are bad engineers/designers, as we frequently didn't apply momentum, EcrossH, reflections, full Maxwell Equations, etc.

I know of some of your designs and that from others (they are successful). So something in that statement regarding bad engineers/ designers is wrong.

When dealing with fresh from school engineers I frequently encountered bad results or good results, but delivered too late (so aren't good in fact). The last category is mostly caused by using approximations that are way over the top, complicating calculations, slowing down/crashing simulations, etc.

Knowing to apply a suitable approximation/model separates the seasoned from the fresh engineers.

Now the original topic (that was output impedance of HF PAs and using
non-50 Ohms coaxial cable) is under a pile of reflections,
interferences, momentum, photons, etc, it becomes clear to me whether
to apply the words "fresh" or "seasoned" to some of the contributors.

> I hope Wim (and others?) will excuse the off-topic drift here. =A0And
> I'm _still_ trying to figure out _why_ anyone would care about the
> output impedance of a PA of the sort used at HF to drive antennas.
> Nobody has ever convinced me that it matters at all, except perhaps as
> academic interest.

Tom, excuses are not required, I consider your reply as an attempt to
get the discussion on-topic again.

> Cheers,
> Tom

With kind regards,

Wim

Hello Cecil,

You keep on luring us (and others) into non-relevant discussions.
Snippet from your posting to Tom:

> From the time (t0) that a PA first outputs a Zg signal to the time
> (t1) that the PA senses its load impedance is NOT zero time. How does
> the PA know what its load impedance really is when it is not Zg?
> Einstein's spooky action at a distance? No, feedback from the load.
>
> Obviously, the PA receives some sort of feedback in real time. What is
> the nature of that feedback? What can it be besides feedback energy
> reflected from the load? (not in zero time, but at the speed of
> light). In the real world, it takes measurable time for the forward
> energy to reach the load and measurable time for the reflected
> feedback (if any) to arrive back at the PA. The load seen at the PA
> source is always an E/I ratio, i.e. a lossless image impedance that
> always experiences a delay if it is not equal to Zg, i.e. it usually
> contains reflected energy.

There must be some (for us hidden) reason to do this.

We are discussing near steady state sinusoidal signals, so amplitude and phase can only vary slowly (if not, other amateurs would not be happy with you). Especially in case of manual load pulling, it doesn't matter when there is a back and forth delay of 100 us (that is 10 km of coaxial cable!!). All such delay actions are fully covered by the concept of impedance (and steady state transmission line theory). We are not discussing wide band systems where a reflected signal may be uncorrelated with the actual output signal.

Wim

Cecil, just HOW do you propose to MEASURE the effect you describe, as seen at the transmitter's output port, using only our HF ham transmitter/PA that transmits a signal with a maximum bandwidth of perhaps 10kHz? If it is going to have the dire consequences you suggested a few postings ago, then it must be trivial to measure...unfortunately, I don't see how, and that bugs me, as one who strives to provide accurate, sophisticated measurement technology to engineers.

Perhaps you missed it, but nobody is disagreeing that the mechanism for establishing a load impedance is reflections in the system of lines and lumped loads attached to the PA output. We are simply saying that, for the bandwidth signals involved, you'll be extremely hard-pressed to distinguish between a load consisting of any number of transmission line segments, along with one or many lumped loads wherever you want along those line segments, and a simple equivalent series RLC.

I suppose it will be lost on most of the lurkers, but it's a bit of a bad joke to deny that one can make valid PA output impedance measurements with a signal very slightly off-frequency (less than 1kHz), and then claim that reflections in a system of maybe a couple hundred feet of coax makes a major difference in how the load behaves as compared with a lumped RLC.

Cheers,
Tom

By the way, what is the impedance of a constant 100W source looking back
into its short piece of internal 50 ohm line?

John

I don't have a proposal and am just pointing out some of the technical
problems associated with some of the methods being proposed. FYI, when
one uses a model that presupposes faster than light propagation speeds
to try to explain something happening in the real world, one should
expect some skepticism - unless one can prove that he is using
entangled photons. :-)

Hello Cecil,

Could you please explain why the lumped circuit approach used by many people across the world presupposes faster than light propagation (as I can't)?

In my opinion it only presupposes that speed of light is not of importance and if it does, you can model that very easy by adding some additional lumped components in many cases.

Just take a circuit diagram of your rig, lumped components all over the place and if there are coaxial cables, they are just for transporting a signal from one place to another place. Did you ever used a circuit simulator, if so, did you model every capacitor, resistor, etc with a transmission line model?

You may evaluate for yourself a CLC section and see what the output versus input does. Of course you could also put it in some circuit simulator. And again you are trying to introduce non-relevancy into the topic.

All that is required looking into the 50 ohm flat coax is that the
voltage be a constant 70.7 volts. V^2/Z0 is automatically 100 watts.
So the source could have any internal impedance under the sun as long
as it supplies 70.7 volts into 50 ohms. Didn't you say earlier that
source impedance doesn't matter?

http://hamwaves.com/antennas/inductance/corum.pdf

"The failure of any lumped element circuit model to describe the real world lies at its core inherent *presupposition*: the speed of light is assumed infinite in the wave equation."

"Lumped element circuit theory assumes that there are no wave interference phenomena present, that is - the currents entering and leaving the circuit element's terminals are identical."

http://www.classictesla.com/download/corum_lumped_failure.pdf

"In fact, lumped-element circuit theory inherently employs the cosmological presupposition that the speed of light is infinite, as every EE sophomore should know."

"Lumped circuit theory fails because it's a theory whose presuppositions are inadequate. Every EE in the world was warned of this in their first sophomore circuits course."

Give me some time and I will compose an example based on EZNEC results for a lumped inductor vs a helical inductor of equal inductance. The results are nowhere near the same.

The example is a 4 MHz series circuit with a 100v source, a 72uH inductance, and a 2570 ohm resistor.

Using a 72uH lumped inductance, the current is the same all around the circuit and is 0.032 amps at -24 degrees, i.e. the source current is 24 degrees out of phase with the source voltage.

Using a 72uH helical inductance, the source current is 0.039 amps at -0.02 degrees, i.e. in phase with the source voltage. The load current is 0.039 amps at -42.4 degrees. The phase shift through the helical inductor is more than 40 degrees.

As you probably know, the phase angles of superposed waves have a drastic effect on the resulting impedance.

Hello Cecil,

Can you describe the complete setup, or post a simple drawing
(including ground path, source and load and position of current and
voltmeters). I think that I can model it by using a lumped inductor
with 2 capacitors (in fact a section of an LC delay line). What is the
total wire length (just curious to know)?

72 uH, seems large for a matching inductor in a PA (at say 4 MHz, just
22 pF to resonate).

I'm not speaking for Wim, but I think we are both saying the following:

* You have a known load
* You have a transmission line with known characteristics
* Is is possible to use a Smith chart to get the impedance at the input
to the transmission line.
* We now know the load applied to the transmitter.

All we need to know we get from the chart. We admit that reflections are
responsible for the impedance transformation from load to line input.
But, we don't need to know anything about the reflection details, energy
content of the line, nor how light would like it.

So, we are saying that the load at the line input can be viewed as a
lumped circuit. So now we have a transmitter loaded with a lumped
circuit for further analysis.

That's all. It's simple.

John

Do you have EZNEC? If so, I can just upload the .EZ files to my web
page.

:-) It's just what I had available - an EZNEC version of a Texas
Bugcatcher 80m loading coil.

It doesn't quite work that well. I gave an earlier example where Wim got the the s11 parameter wrong by an infinite percentage. The s-parameter equations for a lumped circuit vs an impedance discontinuity are nothing alike. Even the IEEE definitions for the two different types of impedances are different. The interference conditions at the impedance discontinuity can be proven to be different than for the lumped circuit replacement.

> That's all. It's simple.

Quoting Einstein again: "Everything should be made as simple as possible, but no simpler." :-)

When you switch to the lumped-circuit model, you are agreeing to faster than light signal speeds, NO superposition of signals, zero interference, zero phase shifts through coils, identical current everywhere, etc. How the heck can you assert and prove there is zero interference inside a source when reflected energy is flowing through it?

So, you're saying that the Smith chart is wrong?

Exactly so, John. Good summary. So long as the transmitter's bandwidth is small enough that you are always operating practically at steady-state conditions, the transmitter can't tell the difference between whatever assembly of transmission lines and lumped loads distributed along those lines you want, and a simple lumped circuit that presents the same impedance as the steady-state value of the jumble of transmission lines out there. (For very narrow-band loads, you might want to use a lumped equivalent that presents sensibly the same impedance as the load across the whole transmitted bandwidth, not just at one point.)

It is NOT that anyone is assuming "faster than speed of light," it's that we're recognizing that the (HF voice-bandwidth) transmitter is slower than molasses relative to the propagation times involved in a couple hundred feet of coax, or probably even a couple thousand feet. The attenuation per foot of the lines we use is high enough that it's just about impossible to deviate significantly from steady-state conditions for the bandwidths we use.

That's certainly not true for pulsed radar signals, or for fast-scan TV, or for other wideband signals. In those cases, you'll probably find it pays to insure the line is matched to the load so there aren't significant reflections, and you may want to arrange the source (PA/ transmitter) to have an output impedance close to the line impedance so it absorbs any reflections that do happen at the load end of the line. (If you want to get fancy, you might use a circulator to insure dissipation of such returning signals.)

Cheers,
Tom

Hello Cecil,

Would you please remind me to the example where I was completely wrong
with S11?

Did you ever DESIGNED some serious electronic hardware? I am not
pointing to using a recipe book or troubleshooting/repair.

> --
> 73, Cecil, w5dxp.com

Regarding your helical; I don't have Eznec. Maybe you can use some
screenshots from it, put some comment to it and put that on website,
so we can view it.

Wim

The Smith Chart is a tool - a blank graph. How could it be wrong?
Like any tool, it has limitations and can be abused.

On May 19, 4:05 am, Wimpie <wimabc...@tetech.nl> wrote:
> Would you please remind me to the example where I was completely wrong
> with S11?

----50 ohm--+--1/4WL Z0=3D100--200 ohm load

s11 is 0.3333 at point '+'. Put it in a box and s11 magically becomes 0.0?

The first s11 is a physical reflection coefficient, the second s11 is a virtual reflection coefficient. The virtual 50 ohm impedance is lossless. All the power is dissipated in the 200 ohm resistor at a reflection coefficient of 0.3333.

> Did you ever DESIGNED some serious electronic hardware?

No, but being a good designer has nothing to do with the present academic exercise. W8JI is a good designer yet concepts like yours led him to "measure" a 3 ns delay through a 100 uH air-core 80m loading coil when the actual delay time is closer to 21.5 ns. That's what happens when one relies on the lumped-circuit model and ignores reflected energy. The relative phase of a standing wave doesn't change with length which gives the illusion that the signal is traveling faster than the speed of light, i.e. zero phase delay.

I will turn the coil example into a brainteaser and post it to my web

page.

Hello Cecil,

Your circuit (lumped inductance example) with 100V input into 72uH
with 2570 Ohms load):

From lumped circuit simulation (Beige Bag PSPICE, version 4
professional):

  I_source =3D 32mA, -35 degrees
  I_load =3D 32mA, -35 degrees

This agrees with hand calculation, all phase with respect to input
voltage.

From simulation, but now a pi filter C=3D6pF, L=3D72u, C=3D6pF, load =3D 25=
70
Ohms
Simulation carried out with same PSPICE package without using
transmission line sections:

  I_source =3D 38mA, -1.5 degrees
  I_load =3D 38mA, -44 degrees.

Total required time for setting up the simulations and guessing the
parasitic components to simulate the actual inductor behavior: about
15 minutes.

As you can see good agreement without using any of the photons, speed
of light, momentum and other issues, just lumped circuit simulation
where some parasitics are added. Of course a can make a better match,
but this doesn't contribute to the discussion.

I hope that some followers or contributors will do the same simulation
in a lumped circuit simulator, so that we don't arrive in a discussion
that I am cheating.

Cecil,

It is very simple, the 1/4 lamba line (100 Ohms) looks into a 200 Ohms
load, so seen from that line, VSWR =3D 2, hence resulting in RC=3D0.3333.

The 50 Ohms source looks into a 50 Ohms load (you can use the quarter
wave formula). This equals VSWR=3D1, so RC=3D0.   I think I wasn't wrong!
As mentioned before, a source (whether PA or small signal) doesn't see
the difference between a lumped 50 Ohms load or your quarter wave line
with 200 Ohms load. Whether or not it is "physical" or "virtual" is
also not relevant, just the complex V/I ratio (we call that impedance)
counts.

The RC inside the line is of no relevance for the PA.

It may be of importance w.r.t. selecting the right model to solve
technical problems. A good example what can happen when selecting
over-the-top approaches is this thread.

Hello Cecil,

I would like to return back to the topic with a brainteaser also. You posted links to some document written by Walt. The first reference (QEX, May-June 2001, http://www.w2du.com/QEXMayJun01.pdf) shows some measuring results using load pulling in table one.

I have a source 100Vp, 4 MHz, sinusoidal, in series with a capacitance of 796 pF (that is a capacitive reactance of 50 Ohms). Would you be so kind to determine the output impedance of this source using load pulling (for example using 51.2 Ohms and 44.6 Ohms). Of course I have no problems if you (or somebody else) use a simulator to save time.

If you (or somebody else) feel uncomfortable with a zero ohm voltage source, you may add 1 Ohms in series with the capacitor.

Did you (or somebody else) expect the calculated result based on load pulling?

With kind regards,

Wim

In that case I have no need of S11 or reflections or light. I only need to know that the Smith chart tells me that a 200 ohm load looks like a 50 ohm load through a 1/4WL-100 ohm line. I made it as simple as possible but no simpler.

John

I understand, Tom, and thank your for your input. Of course, we are discussing an ideal setup, so I did not emphasize those points. But, I know you know that. Nevertheless, thank your for the disclaimers.

Cheers & 73,
John

You just proved one of my points. Inventing impedors that do not exist in reality in order to rationalize the real-world delay through a real-world loading coil is exactly what I have been complaining about. Are the imaginary lumped-circuit capacitors, to which you are forced to resort, part of the actual impedance in reality or a figment of your imagination?

http://hamwaves.com/antennas/inductance/corum.pdf
"The concept of coil 'self-capacitance' is an attempt to circumvent transmission line effects on small coils when the current distribution begins to depart from its DC behavior." About the capacitors you added above it says: "Of course, this is merely a statistical determination appropriate for computations ... and *not at all a physical quantity*."

The reason that the source voltage and source current are in phase in the example is because the load resistor equals the Z0 of the coil which is functioning in transmission line mode with a VF =3D 0.019, i.e. like a transmission line, it is indeed 0.1167 wavelengths long electrically. I have verified such (within a certain degree of accuracy) through bench experiments.

:-) I saw a similar example over a half-century ago - a zero ohm
source that is 100% efficient no matter what the load. A conjugate
match provides enough power to destroy the universe. Question is: If a
source impedance is a pure reactance, can it deliver any power?

Well there you go - my point exactly - it "looks like" but appearances can be deceiving. You and I know that they are not identical because we are smarter than the average bear and the IEEE has different definitions for those two radically different kinds of impedances. We know that it is a virtual image of 50 ohms because no 50 ohm resistor exists in reality and no zero reflection coefficient exists in reality. In mathematical terms, there is no one to one correspondence between a 50 ohm dummy load and a 50 ohm antenna.

Cecil,

Just solve this source brainteaser (that contains the capacitor) with the principles outlined in a reference provided by you. Efficiency is not of importance here, so please don't lure us into new non-relevant issues.

Though its seems just theoretically, I source providing 100W at 4 MHz
with Zout is =3D 1 ohm (or less) can be made with today's components.

First I'll point out that the model Wim used doesn't match "the concept of coil self-capacitance," so it's not clear that the rest of what you wrote is relevant.

Now, what do you do about your coils when you discover that they do NOT behave like a TEM transmission line? Indeed they do not; it's pretty easy to verify from measurements on real coils and real circuits. It seems like now you are stuck, because you (seem to) have a lot of trouble looking at a circuit and understanding what's really important and what isn't, with regard to performance in a particular application. Sometimes it's appropriate to use a model that goes well beyond a simple transmission line model of a coil; sometimes the simple transmission line model is far more complex than you need. See Wim's previous posting about the value of understanding that.

FWIW, I understand perfectly well where the capacitances Wim put into his model come from. I know exactly how I would estimate them from a particular physical configuration, and I suppose Wim does something very similar to what I would. They come very much from the real physical world, not from our imaginations.

Cheers,
Tom

Cecil,

Lumped circuit approach gives a good solution for your brainteaser (maybe against your expectations or hope). It is just distributed capacitance to ground that can be concentrated into 1 or more capacitors if you are well below the first resonance frequency.

In a real application when using a lumped 72uH inductor for calculations, one will find out that the capacitors for a certain application (for example pi-filter section) have to be somewhat smaller then based on the lumped circuit calculation.

Regarding transmission line behavior
It is the reason to mention "without using transmission line sections". Because my PSPICE package also allows use of transmission lines, if convenient I use them. Do you know how I made my first guess for the capacitors? Just by using transmission line theory. BTW, what is the wire length of the inductor in your HF rig (for 4 MHz band)? It is very likely well below the length for the bugcatcher example.

Did you know that many delay lines were/are made by using multiple CLC sections (for example used in oscilloscopes)?

Again, look to the circuits of your rig, do you really think that the design is carried out by modelling each component as a transmission line. The answer is no (for sure).

We have various religions around the globe; I think we don't need another one based on transmission lines! Maybe for you it was wonderful to explore transmission line theory, but for RF Engineers/

Designers (antenna designers included), it is just one of their means
to get the job done.

Cecil,

Lumped circuit approach gives a good solution for your brainteaser (maybe against your expectations or hope). It is just distributed capacitance to ground that can be concentrated into 1 or more capacitors if you are well below the first resonance frequency.

In a real application when using a lumped 72uH inductor for calculations, one will find out that the capacitors for a certain application (for example pi-filter section) have to be somewhat smaller then based on the lumped circuit calculation.

Regarding transmission line behavior
It is the reason to mention "without using transmission line sections". Because my PSPICE package also allows use of transmission lines, if convenient I use them. Do you know how I made my first guess for the capacitors? Just by using transmission line theory. BTW, what is the wire length of the inductor in your HF rig (for 4 MHz band)? It is very likely well below the length for the bugcatcher example.

Did you know that many delay lines were/are made by using multiple CLC sections (for example used in oscilloscopes)?

Again, look to the circuits of your rig, do you really think that the design is carried out by modelling each component as a transmission line. The answer is no (for sure).

We have various religions around the globe; I think we don't need another one based on transmission lines! Maybe for you it was wonderful to explore transmission line theory, but for RF Engineers/Designers (antenna designers included), it is just one of their means to get the job done.

Maximum power transfer occurs when the load is the conjugate of the source impedance. Of course, in this case, when the source is purely reactive, no power transfer is possible with a conjugate match. I don't think our models were designed to handle magical situations so I'm assuming this exercise is designed to waste my time (of which I have precious little left). Come to think of it, didn't you call my examples, "off topic", and refuse to have anything to do with them?

And, I find the lack of stray capacitance in Cecil's model much harder
to believe than the presence of them in Wim's model.

John

Well, Cecil, we've now reached the end. No resistor exists in reality so
no transmitters, waves, light, transmission lines exists in reality.
There is no one to one correspondence between you and sanity.

This is just plain stupid. You only want to argue.

John

Cecil,
```

Lumped circuit approach gives a good solution for your brainteaser (maybe against your expectations or hope). It is just distributed capacitance to ground that can be concentrated into 1 or more capacitors if you are well below the first resonance frequency.

In a real application when using a lumped 72uH inductor for calculations, one will find out that the capacitors for a certain application (for example pi-filter section) have to be somewhat smaller then based on the lumped circuit calculation.

Regarding transmission line behavior
It is the reason to mention "without using transmission line sections". Because my PSPICE package also allows use of transmission lines, if convenient I use them. Do you know how I made my first guess for the capacitors? Just by using transmission line theory. BTW, what is the wire length of the inductor in your HF rig (for 4 MHz band)? It is very likely well below the length for the bugcatcher example.

Did you know that many delay lines were/are made by using multiple CLC sections (for example used in oscilloscopes)?

Again, look to the circuits of your rig, do you really think that the design is carried out by modelling each component as a transmission line. The answer is no (for sure).

We have various religions around the globe; I think we don't need another one based on transmission lines! Maybe for you it was wonderful to explore transmission line theory, but for RF Engineers/ Designers (antenna designers included), it is just one of their means to get the job done.

I agree. Your above posting is just plain stupid. You are stating the opposite of what I have said hoping some readers will not notice. Resistors exist *in reality* e.g. in dummy loads. You are promoting E/I ratios, existing as virtual resistances, to be as real as a physical resistor. Hopefully, no one ever loads his virtual gun with one of those virtual resistances and fires it at you. Question is, would you die or not? It has been said that everyone creates his own reality and it must be true. You guys have created models of reality in your minds that bear very little resemblance to the real world.

In the field of optics, an real image that actually exists in reality is clearly differentiated from a virtual image which is an illusion that doesn't actually exist where it appears to exist. Light waves are EM waves. RF waves are EM waves. You guys are promoting a model that considers virtual images to actually exist at the point where they appear to exist but are only an illusion. I agree with you - that is just plain stupid.

To summarize: Resistors, capacitors, and inductors, defined under the concept of impedors (from "The IEEE Dictionary") are real-world devices with a physical existence - one can pick them up and touch them.

E/I ratios, containing resistance plus capacitive or inductive reactance, are impedances that do not have a physical existence. Their existence is conceptual and exists only in human minds capable of concepts (much like the concept of God).

When you are standing four feet from a mirror and your image appears four feet behind the mirror, you are arguing that you can replace your actual self with an alternate self four feet behind the mirror and everything will be exactly the same. I agree with you - that is just plain stupid.

Actually, what I am attempting to do is discourage your lumped-circuit religion, where a 100 uH, 10" long coil, can propagate an RF signal in 3 ns, and move you guys closer to the reality of Maxwell's equations.

Cecil,

I already expected that you wouldn't solve my brainteaser (so I did it
in advance), Here is the result for the 100V, 4 MHz sinusoidal source
in series with 796pF, load pulling with 51.2 Ohms and 44.6 Ohms:

V_out (51.2 Ohms) =3D 71.5V, I_out =3D 1.396A
V_out (44.6 Ohms) =3D 66.5V, I_out =3D 1.491A

Delta_V =3D 5.0V, Delta_I =3D 0.095A,

Hence Rout =3D 52.6 Ohms.

Power into 50 Ohms =3D 50W.

=A1Really strange!, that a fully imaginary output impedance of -j50 Ohms results in real 52.6 Ohms output impedance based on the scalar load pulling referenced by you.

I also applied complex load pulling (that is taking phase change into account) and Tom's off-carrier injection method to the same source. Both methods put out Zout =3D -j50 Ohms (yes, the correct value).

You are criticizing Tom's method without any solid foundation, but you referenced to a method with very limited application as shown in this simple example.

You are mixing coherent signal theory with non-coherent signal theory (narrow band RF versus unspecified optical), also your reply above has no relevance to PA's for HF amateur service.

Cecil, we have all our specialities and limitations. It is becoming clear that you lack experience in the field of signal processing and RF (systems) Engineering. This is no problem, because many people can live without it. Instead of continuing the way you do, you can better try to grab some of the concepts offered by others. I am sure it will give you better insight in what happens in RF systems, in considerably less time.

Hello Cecil,

I am not addicted to "lumped circuits", I just use the appropriate
model. Many amateurs built and / or designed their own HF PA (and
other circuitry relevant to the hobby). Do you really think that they
all considered every component to be a transmission line?

Transmission lines in general.
I agree with Tom, "Transmission line approach" is also just a model
with limited validity. It all depends on the Engineer/Designer whether
to use it or misuse it.

Yes Wim, I understand your black box, and the voltage-divider action
that occurs when terminated into 50 ohms. But you didn't answer my
question, as you normally don't do. So I'll ask it again, as I did in
my previous post:

"(Vout =3D 212.1*50/(50+100) =3D 70.7V," I asked for the mathematical
basis for this equation. I agree that it's mathematically correct, but
212.1 is voltage, or E, but where does 212.1*50 come from? The
equation appears to be of the form E/R =3D E, which is absurd. In what
equational form is this equation? I'm trying to learn here.
Walt

I apologize for stepping in, Walt, but, maybe this will help:

Vout = 212.1 * (50/(50+100))

In other words, Vout is equal to Vsource times the divider ratio.

I know you know this. I think you just misread it.

Cheers,
John

Walt,

First you should change language, because if you don't understand
something, it is not always the other party who is wrong.

For a voltage divider:

Vout =3D Vin*R1/(R1+R2).

R1 is the lower resistor , here 50 Ohms, R2 is the upper resistor,
here 100 Ohms (inside the black box).  I can't make it easier. Vin =3D
212.1 Vrms.

Wim

Thank you for the clarification, Wim. I was unaware of that equation
relative to voltage dividers. I'm going to have to do some thinking on
that equation before I'll understand the relevance of the numerator,
or how it relates to the calculation.

Walt

Thank you for stepping in, John, as from you and Wim I understand that
that equation represents the voltage-divider circuit. However, I'm
still agonizing over the numerator in the ratio. I just can't fit it
into the voltage-divider concept. Gimme a little time and it will
probably sink in.

Walt

Richard, the text below represents real world better:

"Though it's a red herring typical of Ham-speak, most modern retail
100W RF transmitters for amateur service require to see a very low
impedance at their drains/collectors, a fraction of an ohm
[ editorial: until, of course, it goes to the Z transformer that
precedes the bandpass filter]."

A push-pull 100W PA (non-switching, just a linear amplifier) fed from
13.8 Vdc will produce a voltage swing of about 20Vp at the primary of
the wide band impedance transformer. I know it can be somewhat more,
but with increased IMD.   To extract 100W, you need to create a 2 Ohms
```

load between the collectors (or drains).

This 2 Ohms has no relation with the actual output impedance of the
active devices (as this depends on the impedance seen from the base/
gate, semiconductor process, amount of saturation, etc).

With kind regards,

Wim

On May 13, 5:51=A0pm, Wimpie <wimabc...@tetech.nl> wrote:

> When a source behaves like a 50 Ohms source, it will not rereflect the reflected power back to the load. In other words the forward power generated by the source will not change when changing the load. The reflected power that is absorbed by the source may result in increase or reduction of power dissipation of the active device. It all depends on the change of the integral of V*I (for the active device).

Where is the reflected power that is "absorbed by the source" dissipated? How can a "reduction of power dissipation" be the result? The answer is that if the power dissipation of the source decreases when the reflected power is incident, then destructive interference energy is being redistributed back toward the load. That destructive interference energy includes some (or all) of the reflected energy.

The forward wave is associated with EfwdxHfwd power. The reflected wave is associated with ErefxHref power. The energy in those two waves traveling in opposite directions at the speed of light in the medium must be conserved.

For instance, when the load at the end of an ideal 1/4WL feedline is changed to a short, the forward power is still the same and the reflected power is equal to the forward power. Yet, the source dissipation has been reduced to zero even though the reflected power "is absorbed by the source". In the source resistor, the forward current is equal in magnitude and 180 degrees out of phase with the reflected current and the net current superposes to zero. That's the definition of "total destructive interference" and according to the conservation of energy principle, the energy involved has to go somewhere - so it is redistributed in the only possible direction - back toward the load associated with the "total destructive interference" that occurs in the 50 ohm source resistor.

The main point to this part of the discussion is to realize that the forward and reflected wave energy is flowing through the 50 ohm source resistor because the physical reflection coefficient looking back into the 50 ohm source from a 50 ohm feedline is zero.

FWIW, I've built audio amplifiers with output transistors with f-sub-t around 50MHz. Those transistors certainly would provide decent power gain at the lower frequency HF ham bands. They were used in the audio amp to achieve very low distortion across the audio spectrum (a very few PPM at full rated power output).

One big difference between (typical) audio amplifiers and (typical) RF power amplifiers is in the use of negative feedback. In an audio amplifier, voltage-derived negative feedback yields a very low amplifier output impedance. In almost all RF power amplifiers, little or no negative feedback is used, so the output impedance is generally much higher than with an audio amplifier running similar power and supply voltage to the output devices.

But again, the source impedance of a transmitter is seldom important in the application of the amplifier. What's important are things like the optimal load impedance and the rated power output. I'd put things like distortion specs for a linear amp far above source impedance in importance. If you (the lurking reader) think source impedance is important, please explain in detail _why_.

Cheers,
Tom

Hello Cecil,

Ever looked at the plate current indicator during tuning? I think you did. Here you see that plate loading affects plate current, hence DC input power to the PA.

Just convert the voltage reflection coefficient (as seen by the PA) to an impedance and work this back through the Pi-filter to the plate. Now you can forget the whole reflected power story.

What happens now depends on what the plate sees. Due to internal feedback (grid capacitances) and/or voltage saturation issues, both plate dissipation and average plate current (so PA input power) may change.   Same is valid for solid state PAs also. Changing the load changes device dissipation and DC input power.

I mentioned this in this thread and a similar thread about a year ago.

your question directly: reduction in power dissipation can occur when the impedance as seen from the active devices increases. It will go into voltage saturation, and this leads to a reduction in average (DC) current and integral of V*I product. V can be plate voltage, I can be plate current.

> The answer is that if the power dissipation of the source decreases
> when the reflected power is incident, then destructive interference
> energy is being redistributed back toward the load. That destructive
> interference energy includes some (or all) of the reflected energy.

If some of the reflected wave re-reflects at the cable-PA transition, you will notice this very likely at the forward power indicator. It also shows that in that case the output impedance of the PA isn't 50 Ohms (as is the case with many PAs).

>
> The forward wave is associated with EfwdxHfwd power. The reflected wave is associated with ErefxHref power. The energy in those two waves traveling in opposite directions at the speed of light in the medium must be conserved.
>
> For instance, when the load at the end of an ideal 1/4WL feedline is changed to a short, the forward power is still the same and the reflected power is equal to the forward power.

Fully agree, if the source remains a 50 Ohms source under this massive mismatch.

> Yet, the source dissipation has been reduced to zero even though the reflected power "is absorbed by the source".

I do generally not agree on this one, please convert your Thevenin source to a Norton source. Though the source doesn't deliver any power to the shorted quarter wave line (as its input impedance is infinite), there is still dissipation in the source.

Practical issue (very related to PAs): when you put your shorted quarter wave line directly to a PA with a type of L match (as is used in low voltage solid state PAs), the L match will "convert" this impedance to a very low value, resulting in an near AC short at the drain or collector. This will greatly increase the power dissipation in the BJT or MOSFET.

> In the source resistor, the forward current is equal in magnitude and 180 degrees out of phase with the reflected current and the net current superposes to zero. That's the definition of "total destructive interference" and according to the conservation of energy principle, the energy involved has to go somewhere - so it is redistributed in the only possible direction - back toward the load associated with the "total destructive interference" that occurs in the 50 ohm source resistor.
>
> The main point to this part of the discussion is to realize that the forward and reflected wave energy is flowing through the 50 ohm source resistor because the physical reflection coefficient looking back into the 50 ohm source from a 50 ohm feedline is zero.

> --
> 73, Cecil, w5dxp.com
> "Halitosis is better than no breath at all.", Don, KE6AJH/SK

For the experimenters:
Make this setup: PA =96 forward/reflected power indicator =96 tuner =96 50 Ohms load. Have a means to measure the PA input current.

Notice DC input current and forward power when the tuner is not used (bypassed) and don't touch PA settings anymore. Now activate the tuner and show slight mismatch to your PA (with your tuner). Notice the PA input current and forward power reading. You may need to turn of ALC or other means that automatically change the drive level of the actual power device (valve or semiconductor).

Very likely both PA input current and forward power reading will change.   You may do this at various power levels and not the difference.

With kind regards,

Wim

Hi Tom,

An Answer to one of my questions (and by inference two of them)!

The inference is there is NO transition frequency where source Z becomes trivial/meaningful. Hence, statements alleging correlations at one end of the spectrum must be observed at the other end.

If this is disputed, we (or at least I) would certainly like to see what that transition frequency is.

>One big difference between (typical) audio amplifiers and (typical) RF power amplifiers is in the use of negative feedback. In an audio amplifier, voltage-derived negative feedback yields a very low amplifier output impedance. In almost all RF power amplifiers, little or no negative feedback is used, so the output impedance is generally much higher than with an audio amplifier running similar power and supply voltage to the output devices.

Well, at the RF finals deck, before the Z transformer, there is slight to no difference in output impedance. Both are sub-Ohm.

>But again, the source impedance of a transmitter is seldom important in the application of the amplifier.

This seems at odds with other writers - if it is an AF amplifier. And yet none seem to be able to describe the transition frequency for identical designs (such as yours above, or as close to it as practicable) where it DOES become important (higher output power, as if any Ham would snub that advantage if (s)he could snip out the Z transformer in the rig).

One still unanswered question remains that if a low output Z is so beneficial to achieving higher output power (a claim that none seem ready to dispute), then why the step up in Z from the finals deck to the output connector? I have read an explanation from Wim, but it fails as an argument for AF where a similar mismatch between source and load is observed - and yet this mismatch is the greatest quality for an amplifier since sliced bread.

AF - RF   A curious tennis match here where what going over the net in this game is a golf ball in one direction, and a basketball in the other.

>What's important are things like
>the optimal load impedance and the rated power output. I'd put things
>like distortion specs for a linear amp far above source impedance in

>important, please explain in detail _why_.

The self-same NEGATIVE feedback, lacking in retail rigs, would accomplish any form of improvement at the cost of what H.W. Bode called "noise gain." The dollar cost is not inconsequential. Not much more detail is needed for the average Ham.

For the better than average Ham, the increase in NEGATIVE feedback, goes directly to lowering:
Gain,
Power out (as a function of following gain),
Bandwidth (as a function of following gain),
Distortion,
Power supply disturbance,
Noise,
Input Z (or through clever design, raising it),
Output Z (or through clever design, raising it),
while increasing cost in near or GREATER proportion.

Every Ham knows the adage that there is no such thing as a free lunch, and the marketplace enforces that without exception.

Let's see here, a reported source Z as low as 15 (let's just call it 20) Ohms with 100W into 50 Ohms. I have read an explanation that this is impossible (or improbable) for RF from a retail HF rig (such as a TS440), but achievable at AF.

Meanwhile, back at the tennis match....

At the risk of removing a snippet from context, and simplifying in language and construction:

BELOW a
     transition frequency
audio amps source rated at LOW Z sourcing high power into HIGH Z loads work.

ABOVE that
     transition frequency
retail Amateur transmitters source rated at LOW Z sourcing high power into HIGH Z loads
     do not work.

I wonder if that works (sic) with these statements reversed?

Bonus question:

What is the transition frequency?

Both questions can be simply answered: the first with a binary

response, the other with a numerical response (two place precision is
OK - even one place precision is sufficient).

This is the price of subject drift:
    "AF amp specs as proof of RF amp performance."
What a work of obscurity.

You can challenge the premise, of course; but to reduce rambling
thoughts driven by subject drift, and to remain on topic:

Hello Richard,

Part from original posting (salmonella):

"Something I haven't seen is a discussion of the source impedance of the transmitter. My curiosity was piqued today as I took some baby steps into EZNEC. A particular antenna had such-and-such VSWR if fed with a 50-ohm cable and a different value if fed with a 75-ohm cable."

The subject is output impedance of a PA. I made a clear statement regarding this in my first reaction.

Part of your posting:

> Though it's a red herring typical of Ham-speak, most modern retail
> 100W RF transmitters for amateur service have a very low output
> impedance, a fraction of an ohm [editorial: until, of course, it goes
> to the Z transformer that precedes the bandpass filter].

The above text is basically on topic, but not correct, so I suggested a correction. In my opinion, the push-pull example is OT also.

Some snippet from you posting:

> You can challenge the premise, of course; but to reduce rambling
> thoughts driven by subject drift, and to remain on topic:

Are you pointing to the rambling in your own mind?

Richard, who made that claim regarding that low output Z is so
beneficial? I didn't, so I also did not explain it. I only said that
many PAs don't operate under conjugated match (or even were not
designed to operate under it). This is valid for audio also.

On May 14, 1:56=A0pm, Wimpie <wimabc...@tetech.nl> wrote:

> Now you can forget the whole reflected power story.

Which is exactly what most people do - just forget the problem and hope it will go away. Some have said just to calculate the voltage/current and the energy (or power) will take care of itself. What this requires is ignorance of the well-known laws of physics from the field of optics. When one understands the laws of physics that effect the boundary conditions for RF waves including the role of interference, all of the component energies can be easily tracked through a system in the same manner the track irradiance through an optical system because they cannot measure the voltages and currents. Method#1 is the way most RF engineers analyze a problem. Method#2 is the way optical physicists are forced to solve the problem.

Method#1: Calculate the voltages and currents and superpose them. (One way is using s-parameter voltage equations.) Calculate power at the end of this process.

Method#2: Calculate the irradiances (power densities) and merge them together using the irradiance equations. The irradiance equations are what one gets when one squares the s-parameter normalized voltage equations.

When you say "forget reflected power", you are asking people to forget the ExH power contained in every EM wave. You are asking people to forget that EM waves must necessarily travel at the speed of light in the medium, i.e. component EM wave energy cannot stand still in standing waves. You are asking people to forget the conservation of energy principle.

Earlier I suggested that we concentrate on a simpler lossless example that doesn't involve the source impedance at all. It doesn't matter what the source impedance is. All that matters is that the source is delivering 70.707 volts to the 50 ohm feedline. Here it is again:

100W--50ohm--+--1/4WL 100ohm--200 ohm load

During steady-state, Pfwd is 100w and Pref is 0 watts on the 50 ohm line. Pfwd is 112.5w and Pref is 12.5w on the 100 ohm line. Exactly what happens at the Z0-match point '+' to reverse the flow of that 12.5w reflected power wave? (There are no RF source or DC supply arguments behind which to hide.) The reflected voltage reflection coefficient at point '+' is -0.3333, i.e. the negative of the forward voltage reflection coefficient at the load.

The ExH power (Poynting vector) in the reflected wave from the load is 12.5 watts. It is necessarily traveling toward the source at the speed of light in the Z0=3D100 ohm medium. It necessarily contains measurable real-world energy and momentum. Exactly what happens at point '+' to reverse the momentum and energy flow of that reflected EM wave? All the arguments in the world about what happens in the source has not answered that question and this example doesn't involve the source at all.

> I do generally not agree on this one, please convert your Thevenin
> source to a Norton source.

Sorry, that particular source was not my choice but was instead W7EL's choice in his food-for-thought series. He specifically states he is NOT talking about any equivalent circuit but is instead talking about a good approximation to a real-world source with a 50 ohm source resistance.

I do not see how the above energy flow problem/example can be solved without an understanding of the principles of interference (covered in section 4.3 of "Reflections" by Walter Maxwell. If you can adequately answer the questions without any direct or implied reference to interference, you will be the first I know of on ham newsgroups to have done so. Hint: squaring the s-parameter equations yields those interference power terms. If you choose not to respond to this simpler example, I will understand your reasons based on "forgetting reflected power".

This is in regards to the thread on qrz.com.

I have started sending this to members of the site. Are you going to address this issue? If not the next step will be the sponsers. I wonder what a capitalistic business will think of the sensorship on an opinion page. I'm not going to stop this campaign untill you reign in your mods. There is no reason that they just up and shut down some of the threads that they shut down. And if a thread is shut down there should be more of an explanation other than, "I don't like it. I can shut it down and I deem it so". Address this issue openly on the board. If not. Let the games begin.

Opinions and Editorials
New Hams

If this is what the MEMBERS of the board want to discuss on the, now read this part twice if you must. "Opinions and Editorials" section of the forum than we will do it regardless of what you say, do or think. These are our OPINIONS on the issues of the day. Whatever that may be. You and the other mods need to grow some rhino skin and just learn to ignore posts that you don't care for and stop being a tin star sheriff who thinks his ass weighs a ton. Build a bridge. Get over it and your self. We all ignore posts that we don't care for. We are adults.

Evidently you are incapable of doing so. and don't give me this crap about it being for the greater good of the masses. You sobs sound more and more like our elected officials every day. We will, for the most part self regulate ourselves. I see it as just a power trip for you and the other mods. I do agree in some regulation on the board but on a forum that has the word "OPINION' in it. Come on, lets be real. It will run it's course all on it's own. I speak for more than a few on the board. You think you are way more important than you really are. Open the thread back up and watch what happens. It will get old eventually and revisited occasionally but so what!? It is an OPINION page! Just because you don't care for it is pretty much saying that we are only allowed to post things that suite your opinions. And that sheriff is utter BS. When you lay down in bed tonight think about a purple horse, first that is something that you will never get out of your head and second think about how utterly controlling you are being on a forum titled "Opinion". Think man think! What your doing here is no way to run a board. It is a power thing on your end regardless of how you want to justify it.

It is strongly urged to reconsider the closing of the thread and others that have been closed for reasoning that can only be understood by the mods. I guess you are a little like the Government, You seem to think that only you know what is good for us. What a bunch of crap.

Go to the site and see for your self. Hammer the point home. Just asking for a little help fellow hams. www.qrz.com

I don't get why you're so hung up on some transition frequency between "RF" and "audio" amplifiers. You're looking at it in the wrong dimension. Think instead of the loads they drive. Speakers (the usual load for audio power amplifiers) work best when driven by a voltage source, so audio amplifiers are designed to look like voltage sources. With antenna systems, it doesn't much matter what the source impedance of the driving amplifier is -- as long as the transmitted bandwidth is small compared with 1/(transmission line time delay) [question to ponder: why would I care about that?] -- so RF amplifiers of the sort we normally use are simply not designed with an eye toward providing any particular output impedance.

You're probably well aware that there are times when I'm personally extremely concerned about providing an RF source that has a well-controlled output impedance (pretty much always 50 ohms, just because of how it's used, but could just as well be 75 ohms, or 100 ohms balanced, or some other specific impedance). That's not the case for the lion's share of ham applications, not even in sources used for simple impedance measurements. There are a few situations in which a ham might legitimately care about transmitter/amplifier output impedance, but they are relatively rare. I'm willing to listen to arguments to the contrary, but have yet to see any convincing ones.

Be careful what you say about the effects of negative feedback added around an amplifier... (That could be a reasonable topic in another group, but not in this thread, and probably not even in this group.)

Cheers,
Tom

Not sure exactly what thread you're referring to, but qrz.com is a not a
public forum, it is a privately owned website, so, the owners can do what
they want with it.

Now I get it... you're the owner of QRZ, and you don't like what some of
the moderators are doing?

It is a 100 ohm feedline. The impedance at the + point looking toward the load is 50 ohms. The 100 W source will see the first 50 ohms and then the impedance at the + point. The total impedance seen by the source is therefore 100 ohms. A 100 W source will deliver 100V to this 100 ohm combination and 50V of it will appear at the + point. Where does the 70.707V come from?

John

Just think of it this way, in NGs, if you don't like to view
something/someones-text, you simply plonk them.

On a private site, if you don't like what someone else says, you can
stop everyone else from seeing what they say -- IF you are a moderator.
  (Moderated NGs serve the same function(s) i.e., you can control what
other people say, and who views it.)

Your only error is giving others the right to censor what you see, and
then complaining about it!  If you don't like it, don't empower them ...

Regards,
JS

Hello Cecil,

I'm rather familiar with S-parameters and unbounded EM phenomena. We are discussing coaxial cables with very small diameter with respect to wavelength, therefore full TEM condition is applicable, even some small distance left or right from a discontinuity. So you can fully replace E cross H by a voltage and current approach (as is used in any vector network analyser).

Regarding impedance, reflection coefficient and interference issues; when you know one of the two (and Z0), you can calculate the other (of course you need to consider phase). All interference issues are accounted for in Z, given a transmission line impedance (Z0).

Transmission line theory is not a goal, but just a means to reach your goal. It is fully acceptable to convert Ref.Coef. to Z (and vice versa) to efficiently solve your problem. So when you convert an RC to a Z, you can forget all transmission line calculations that you used to find that Z. As Tom mentioned, we are discussing narrow band systems, not wide band transmission systems.

I am not ignoring a problem (as you suggested), I am just using the right tool to solve a problem. I remember from several people, the best Engineer is the one that knows what things he has to take into account and what things he can ignore. You introduced optics here, are you going to introduce QM also to show that I (and some others) are completely wrong w.r.t to PA output impedance?

Cecil, I think you have sufficient knowledge to form an opinion without hiding behind others. You also have the equipment to figure out some things yourself, and I gave some hints to help you. The only question is, are you willing to do this?

With kind regards,

Wim

I said: "All that matters is that the source is delivering 70.707
volts to the 50 ohm feedline." That would be at the source SO-239
terminal to PL-259 50 ohm coax junction. I did *NOT* say there is
70.7v on the Z0=3D100 ohm feedline. There is indeed 100 volts on the
Z0=3D100 ohm line.

The source is Z0 matched to 50 ohms and is
delivering 70.707 volts and 1.414 amps to the 50 ohm coax.
70.7/1.414=3D50 ohms. 70.7*1.414=3D100 watts.

Here is a better diagram:

http://www.w5dxp.com/enfig1.gif

Pfor1=3D100w, Pref1=3D0, Z01=3D50 ohms, Z02=3D100 ohms and 1/4WL, Load=3D20=
0
ohms. Everything except the load is lossless.

I apologize if my one line diagram was confusing. It is extremely
difficult to draw ASCII schematics using a proportional font.

I'm sorry, Wim, that is just not true. When you convert a V/I ratio to a lumped circuit impedance, you are switching models in mid-example and it changes everything in one direction (while keeping conditions the same in the other direction). Switching to a model that doesn't recognize reflections at all when a question about reflections arises is an obvious logical diversion. The lumped-circuit model does not recognize reflected energy and therefore does not allow the tracking of reflected energy. The distributed network/wave reflection model does allow for the tracking of reflected energy and was developed because of the limitations of the lumped circuit model.

I will buy your assertion that one can use voltage and current to achieve the same thing if one is careful not to violate the known laws of EM wave physics. In my example, the reflected power on the 100 ohm line is 12.5 watts. The reflected voltage is 35.35 volts. The reflected current is 0.3535. The reflected voltage and reflected current are 180 degrees out of phase so the power is real, i.e. cos(180)=3D1.0, and the reflected wave has a Poynting vector magnitude of 12.5 watts (per coax cross-sectional area).

In my very simple example, there is no reflected power on the 50 ohm feedline yet there is (35.35)(0.3535)=3D12.5 watts of reflected power from the load incident upon the 100/50 ohm impedance discontinuity. I ask you again: Exactly what phenomenon of EM wave physics causes the reflected wave to *reverse* its momentum and direction of energy flow when the magnitude of the reflection coefficient is 0.3333? As long as you refuse to answer this simple question about such a simple example, this discussion will go nowhere.

> Cecil, I think you have sufficient knowledge to form an opinion without hiding behind others. You also have the equipment to figure out some things yourself, and I gave some hints to help you. =A0The only question is, are you willing to do this?

If you cannot answer the simple question about what happens to the reflected energy at a simple passive impedance discontinuity, I am not about to trust your assertions about what happens inside an active source. Trying to introduce a more complicated example while refusing to deal with the very simple example that I provided is an obvious and typical logical diversion. Again, I am not going to cooperate in your attempts at diversions. If you don't know why reflected energy reverses momentum and direction at a passive Z0-match, just say so.

Here's an easier example: Two EM waves superpose in a Z0=3D100 ohm environment. Each wave is 100 volts at 1 amp =3D 100 watts. The phase angle on wave1 is +60 degrees and the phase angle on wave2 is -60 degrees. The superposition results in a new wave of 100 volts at 1 amp =3D 100 watts with a phase angle of zero degrees.

We superposed two 100 watt waves and the result was one 100 watt wave. What happened to the other 100 watts?

Hello Cecil,

I answered a simple question requested several times by Walt (I had to
reply to it!). It wasn't my statement but I did it. The solution I
gave involved both lumped circuit theory (to calculate the net power)
and transmission line theory (to calculate forward and reflected power
in a 50 Ohms environment).

Even other people had to help Walt to understand a voltage divider
(the 212.1*50 issue).   Maybe you can comment whether my simple
solution (not involving momentum, Poynting vector or optics) is
correct or not.   I am familiar with the use (and mis-use by others)
of the Poynting vector, but I don't discharge 10 kJ through a mosquito
when using a newspaper does the job also.

Regarding reflections:
Does a PA see difference between:

1. 100 Ohms lumped circuit load
2. RC =3D +0.33333 (for 50 Ohms reference)
3. VSWR =3D 3 (voltage minimum, for a 300 Ohms reference)

The answer is no, all can be converted to 100 Ohms lumped circuit.
What is in between the PA and the actual load is not relevant, what
matters (for the PA) is what it sees at its SO239 socket.

> degrees. The superposition results in a new wave of 100 volts at 1 amp
> = 100 watts with a phase angle of zero degrees.
>
> We superposed two 100 watt waves and the result was one 100 watt wave.
> What happened to the other 100 watts?

If you want this question answered, please open a new thread as it is
not relevant to the original question.

Maybe people will ask you a circuit diagram showing the sources and
the combiner circuitry to enable calculation of the net power
delivered by each source. Otherwise people may consider your problem
as a single incident wave problem (as for these type of steady state
signals you first add complex amplitudes, then calculate powers).

I did respond to Walt's request because it is on topic and I stated
that such thing can happen (without given a numerical example).

Lumped circuit theory presupposes that waves do not exist and that RF energy travels instantaneously, faster than the speed of light. You seem to be ignoring the numerous laws of physics violated by the lumped circuit theory. You also seem to be ignoring the fact that when lumped circuit theory yields different results than the distributed network theory, distributed network theory always wins because it is closer to Maxwell's equations.

I gave an earlier CLC Pi-Network Tuner example that proved the lumped circuit model fails when reflections are present. EZNEC results are nothing alike when using the lumped inductance option vs the helical wire option for an inductance in a standing wave antenna.

> If you want this question answered, please open a new thread as it is
> not relevant to the original question.

Asserting that it is not relevant for the purpose of diversion will not make it go away. If one cannot understand, explain, and solve the simplest passive interference problem, how is one ever going to understand, explain, and solve the multiple levels of interference possible within an active source being invaded by reflected energy? If one cannot add one plus one, one is not likely to be able to add two plus two and something akin to that is what I am seeing here. Until one understands exactly how a Z0-match reverses the direction and momentum of a reflected wave, one will not understand what is happening inside a source with incident reflected energy. What is actually happening in reality is revealed when one sticks with the distributed network/wave reflection theory throughout the analysis. People who whine that such is too difficult have to be satisfied with a certain level of ignorance and inaccuracy.

Okay, so your source really looks like a a 100 W generator with no internal impedance but which feeds a 50 ohm line internally. Since the 200 ohm load appears as 50 ohms when fed with a 100 ohm 1/4WL line, there is a match and all the power appears at the load. In that case I agree with your 70.7 volts since 100 W into 50 ohms will result in that voltage.

But I have no need of reflections. The fact that a 200 ohm load appears as a 50 ohm load at the input of a 1/4WL 100 ohm line takes care of all that for me.

73,
John

Sorry John, you can't cut it without the reflections. They may be
invisible to you, but they're there doing the work. The 1/4wl line
transformer works only with reflections. If you'll give me your email
address I'll send you a graph showing how the reflections perform the
matching. The actions of the reflections from either end of the

transformer is what performs the matching function. The action of the
reflections is as necessary to the function as breathing is to life.
Believe it!!!

Walt

There's no argument/discussion about that. The question is: Exactly
what happens at the 50 ohm Z0-match to reverse the direction and
momentum of the reflected wave resulting in no reflections on the 50
ohm line? Hint: it is exactly what happens with non-reflective glass
where the 1/4WL thin-film coating cancels the reflections through

destructive interference. Why not alleviate ignorance by taking advantage of those well understood facts of EM wave physics from the field of optics?

Cecil,

It seems that you on purpose remove/ignore things that you don't like, but (you know) are true.

A CLC pi filter doesn't know the difference between:

1. 100 Ohms lumped circuit load
2. RC = +0.33333 (for 50 Ohms reference)

3. VSWR = 3 (voltage minimum, for a 300 Ohms reference)

It seems you don't want to notice that.

That it is convenient to use transmission line theory to calculate the load as seen by a PA when transmission line sections are involved, is OK, I didn't deny that.

That lumped circuit theory has limitations is fully understood. Frequently transmission line effects are modelled using parasitic L and C additions yielding accurate models valid up to GHz frequencies (depending on the size of the component). We are below 30 MHz (for this topic).

Here the experience of the Engineer comes into play: when you can use a lumped circuit model and when you need to use transmission line models (the particle/wave issue is similar)?

A helical inductor of an antenna no longer small w.r.t. wavelength may be better modelled with transmission line theory, but that is OT. Even the L of the CLC filter, you can model with a lumped circuit equivalent with more than sufficient accuracy. This is daily business for manufacturers of inductive components.

Generally, converting results from transmission line models to impedance in combination with lumped circuit theory to calculate the load as seen by the active device, is daily practice. Especially here, as we are dealing with narrow band signals and don't have to model the behavior for harmonics. But for some reason you don't want to see that, and you elevate transmission line theory to a goal.

So again, once you did the conversion to Z, you no longer have to worry about transmission line issues in the load or cabling (including reflection coefficient) when treating your PA's CLC pi filter.

Now speed of light becomes important in a CLC pi filter for a HF PA, when becomes "Gaussian" of importance (and may lose all the readers of this topic)?

With kind regards,

Wim

It is not worth wasting my time to notice since *everyone* already knows that a CLC pi filter is not alive and doesn't have a brain so it must necessarily be dumb as a dead stump. You, OTOH, hopefully being smarter than the average CLC pi filter, should know that the conditions existing within a resistor are different from the conditions existing within an antenna with the same feedpoint impedance. Hint: If you don't know what is in the box, alleviate your ignorance by looking inside the box. If you put on the blinders and refuse to look, then you will make errors like you did earlier while measuring an s11 of zero when it was actually 0.3333.

> equivalent with more than sufficient accuracy.

When the task is to determine the exact delay through the inductor,
how the heck can the lumped circuit model tell you that?

Wim, I forgot to note that using your stated methods, W8JI "measured"
a 3ns delay through a 10" long, 2" diameter, 100 turn, 100uh, 80m
mobile loading coil. Doesn't a 4 MHz RF wave traveling the length of a

large 100uH air-core 80m loading coil in 3 ns give you some pause for
reconsidering your methods? Every wonder why computer manufacturers
don't install 100uh coils in series with their computer bus lines to
speed up their computers? :-)

Just via the capacitance to ground (for example a CLC model of an
inductor well below the first self resonance frequency). But when
looking to a PA, there is often an additional capacitance left and
right of the inductor that causes the most of the phase shift. I did
some tesla coiling, so I am aware of the various models for single
layer inductors. You are further drifting away from the main subject
(PA output impedance and what mismatch will do).

Actually, you are further drifting away from basic fundamental EM physics and I am not in the mood to follow you. Since you do not understand the basic fundamentals of EM wave interference, you cannot possibly understand what is going on inside an active source with invading reflected energy. You might as well be arguing that God causes everything because your lack of the understanding of the basic physics of interference causes your concepts to resemble religion more than anything scientific. That's not an ad hominen attack, just an observation based on the technical ignorance of EM wave interference that you have presented here on this newsgroup. Sorry for being so blunt but anyone who chooses to be ignorant, when there is knowledge available, doesn't deserve much respect, IMO.

Since you have failed to answer the simplest of questions about passive circuits, exactly what makes you an expert on active circuits?

Transition time, 1/f?

The point is the poor attempts to build a design argument against one
(RF) with the other (AF). Your response of using RF transistors for
AF application in nearly identical topologies suited the point: there
is NO transition frequency.

>Think instead of the loads they drive. Speakers (the
>usual load for audio power amplifiers) work best when driven by a

>voltage source, so audio amplifiers are designed to look like voltage sources. With antenna systems, it doesn't much matter what the source impedance of the driving amplifier is -- as long as the transmitted bandwidth is small compared with 1/(transmission line time delay) [question to ponder: why would I care about that?]

Everything to that last point was fine. I can well read the stylistic irony and I wouldn't project that it was a curious hang up.

> -- so RF amplifiers of the sort we normally use are simply not designed with an eye toward providing any particular output impedance.

And yet challenges abound when one (Z) is chosen for any particular design quality.

>You're probably well aware that there are times when I'm personally extremely concerned about providing an RF source that has a well-controlled output impedance (pretty much always 50 ohms, just because of how it's used, but could just as well be 75 ohms, or 100 ohms balanced, or some other specific impedance).

All perfectly reasonable choices, and driven by engineering and application decisions too.

>That's not the case for the lion's share of ham applications, not even in sources used for simple impedance measurements.

?????

> There are a few situations in which a ham might legitimately care about transmitter/amplifier output impedance, but they are relatively rare. I'm willing to listen to arguments to the contrary, but have yet to see any convincing ones.

The length of any source Z thread more than proves your point about its care. Which is to say, few care (there we agree across the population of Hams), and there are those few who are vehement about not caring.

>Be careful what you say about the effects of negative feedback added around an amplifier... (That could be a reasonable topic in another group, but not in this thread, and probably not even in this group.)

I'm quite careful about the effects of negative feedback added around an amplifier. Dare I say that we can be thankful there are none vehement about not caring about that too?

Wim, I offered a corrected thread reference, asked you if you had a threaded newsreader to respond in-thread, and here we are in another branch.

> I only said that
>many PAs don't operate under conjugated match (or even were not
>designed to operate under it).

You are being humble, you've written much more than that.

>This is valid for audio also.

Valid for diesel engine design, I suppose, too. Unfortunately, introducing distraction to the Subject line brings increasingly distractive responses.

However, I enjoy distraction and I can wrap it back to topic:

For instance, AF transmitters were used during WWI for (literal, through the) ground communications. Shall we expand on that history that IS relevant to Transmitter Output Impedance?

References:
http://www.qsl.net/vk3gjz/EarthComs/Artillery%20LOI.pdf
http://www.qsl.net/vk3gjz/EarthComs/GroundComs.pdf
and more....

I dare say that these links, and more, can return the discussion back to Source Z matching that is intuitive, uses very real resistance, and no appeals (at least back then) to reactance.

Cecil,

For Walt I made an exception, but I normally don't do someone's
homework. I also don't spend my time solving non-relevant problems; I
have more interesting quests waiting. If you show up with a relevant
quest, maybe I am willing to dive into it.

I am not calling myself an expert, I just designed some PA's, ranging
from kHz to GHz and from mW to kW, some of them with efficiencies to
over 95%. Together with antenna design and consultancy it assures me
that at the end of each month I have some money left.

With kind regards,

Wim

> If you show up with a relevant
> quest, maybe I am willing to dive into it.

Wim, here is why my questions for you are more than just relevant. It is imperative that someone lecturing us on happenings inside that PA RF volcano be able to understand what is occurring during a passive event involving forward and reflected EM fields and waves occurring at an impedance discontinuity outside of a PA.

Two of the physical quantities that must be conserved are energy and momentum. EM RF fields and waves contain both energy and momentum which must be conserved. I have asked you to tell us exactly what laws of physics govern the reversal of the momentum and direction of energy flow at a Z0-match at a passive impedance discontinuity in a transmission line. You have refused to do so and asserted that such is irrelevant. I contend that I could not have asked a more relevant question - thus the reluctance to provide an answer.

The answer to the question is contained in my energy analysis article at:
http://www.w5dxp.com/energy.htm
A passive Z0-match relies on superposition of waves accompanied by interference effects to explain the reversal of reflected wave energy direction and momentum. Walter Maxwell has called the process a "virtual open-circuit" or a "virtual short". In my article, I explain how it is a two-step process involving normal reflections and interference patterns at the impedance discontinuity. It works exactly like non-reflective glass covering a picture with its 1/4WL thin-film coating where two sets of reflected light waves undergo destructive interference toward the viewer and, honoring the conservation of energy and momentum, reverse their direction and momentum and flow in the opposite direction toward the picture. This is a well-understood phenomenon from sophomore physics 201. Why most RF engineers don't understand this simple physical process involving EM wave interference is beyond belief. Here's the Florida State University web page again:

micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

Set the java application for opposite phase and when the result is zero, scroll down to the bottom of the page to find out what happens to the energy components in the two waves that cancel to zero. Those energy components "are redistributed to regions that permit constructive interference" just as they are at a Z0-match in an RF transmission line where there are only two possible directions for RF energy flow. For every destructive interference event in one direction, there will be an equal magnitude constructive interference event in the opposite direction. At Walt's "virtual short", total destructive interference energy toward the source is redistributed as constructive interference energy back toward the load.

I studied this subject in my EE courses at Texas A&M during the 1950's. The textbook was: "Fields and Waves in Modern Radio", by Ramo and Whinnery, (c) 1944, 1953. The subject is covered under "Quarter-Wave Coating for Eliminating Reflections" in the chapter titled: "Propagation and Reflection of Electromagnetic Waves".

Hello Cecil,

I am familiar with quarter wave (and multi layer) coatings to reduce reflection. I am not waiting for a lecture on (un)bounded wave propagation. If I don't have something present in my mind, I know where to find it.

As mentioned earlier, you can convert all the wave phenomena in the coaxial feed line to impedance as seen by the PA. You are unnecessary complicating things, hence loosing more public that may have interest in this topic.

Maybe you (and other people) should carry out the experiments I

suggested in this thread (looking to forward power, net power and DC
input power versus small load mismatch [normally referenced to 50
Ohms]).

With kind regards,

Wim

Wim, I'm amazed that you don't find the more-detailed explanation of
how impedance matching occurs via wave interference of any value. Many
RF engineers have traditionally believed that a PHYSICAL open or short
circuit is required to produce a reflection. As a professional antenna
engineer with RCA in 1973 I discovered and published the wave
mechanics that produces the VIRTUAL open and short circuits that are
required for achieving an impedance match. I took bashings from those
traditional engineers, who said reflections cannot be engendered by
wave interference, until they studied my data more carefully and
finally agreed I'm right. Remember, James Clerk Maxwell also had his
detractors until they finally saw the light.

Walt

Hopefully you realize that if anything of that nature is happening inside a PA, then your source impedance calculations can be off by magnitudes.

Richard, the point I missed until rereading your post, is that there is total re-reflection of the reflected wave at either the output of the correctly-adjusted pi-network, or at the output of the antenna tuner, not the same mismatch as between the line and the load.

Walt

If, as you have posted, dissipation occurs only at one end of the transmission line -- which presumably for the most useful benefit would be at the end of the line opposite the source, e.g., the load -- and the incident power generated and delivered to that line by the final r-f stage in the transmitter is a constant, then how could "damage to the tube" occur?

Just to note that as a field engineer for RCA Broadcast for many years I have had to troubleshoot and repair failures that occurred in transmission lines, transmitters, and output networks that resulted from reflections -- either from within the transmission line alone, or together with the load connected at its far end.

RF

> I calculate it as 100w. 100/111.11 =3D 0.9000.

Yes, Walt, 100/111.11 =3D 0.9.

But a transmitter generating 100W does not deliver 111.11 watts in the original incident wave arriving at a load VSWR of 2:1 w.r.t a lossless transmission line used to convey that power. It delivers only 100W.

Of that 100W, 88.889W is absorbed by the load, and 11.111W is reflected back to the source.

THAT is where the 88.889W comes from.

Also note that 0,9 does not equal 0.8889.

Hi Richard,

Note how you were careful to specify "phase coherent."

This is dangerous to speak of power in this way, energy would be better, but I will proceed with caution thrown to the winds:

When the reflection hits the transmitter port, it sees the conjugate of the load. As the load was 2:1 (and trusting everyone's math with my own rounding) this means that the transmitter port also presents a 2:1 mismatch at this near end of the coax. Some (10%) of the power in the reflection is re-reflected to the load. Some (90%) of the power in the reflection re-enters the transmitter to add to the next cycle of power going out. In this scenario, that amounts to 9W going into and being coherently impressed upon the tube. The transmitter, then, becomes a buck-boosted 109W source conjugately matched into a 2:1 mismatched load.

9 additional watts at the plate isn't much, but I dare say there are many problems with transmitter tolerances even if you could tune into a short, or an open. Yes, somewhere the SWR meter says everything is hunky-dory, while the smoke is poring out.

Another way of putting it is saying the ringing line is holding 10W until it is dissipated. So far, only the antenna qualifies as dissipation.

Through the magic of Integral Calculus, all the bits and pieces ringing around the system sum up to the whole numbers we started with.

No doubt this will provoke examinations, re-examinations, cross-examinations, innuendo, rants, and raves (or possibly disdainful silence) - something for everyone to enjoy. ;-O

Yes Richard, I'm familiar with your work at RCA Broadcast Div.
However, in my posts I'm concerned only with tube rigs used in the
Amateur Service. In these rigs reflected power doesn't cause
overheating, or other damage to the tubes. But I'll qualify that
statement--if the pi-network is originally resonated into, say, a
dummy load, and is then switched to a mismatched line without
retuning, the reactance appearing at the input of the mismatched line
detunes the network and the result is the same is if the network was
left off resonance initially. As you well know, a mis-tuned pi-network
results in excessive plate current, which, if high enough will damage
the tube. Consequently, it's the mis-tuning that causes the damage,
not the reflections per se.

Incidentally Richard, I was also an electrical engineer with RCA, from 1949 thru 1980, first at the RCA Labs in Princeton and beginning in 1958 with Astro.

Walt

How far behind the driven element should the reflector be?  A quarter
wavelength?

Hmmm...!  :-)  That might be interesting, too.  Feed them 90� out of phase?

Think I'd need some kind of a balun to get the impedences to match?

Apparently you have never had to repair the components of a transmitter PA, an output network, or a transmission line that arced over and/or melted down due to load reflections (coherent, or not).

Hi Walt,

The mismatch, of the reflection wave approaching the transmitter, is seen at the antenna/tuner connection. Hence we have a reflection there back to the load.

In regard to solving the transmission line problem where the mismatched load acts as the source of energy (found in the reflection); then that energy must travel to meet a matching load where the load (our transmitter) complete takes it in, or a mismatch where some energy passes into the load (our transmitter) and some is reflected according to the conventional mechanics of mis-matching.

I take this step given the evidence of physics and reflection at even the most specular of surfaces. There is some portion of the energy that exists within a quarter wave behind/beneath the surface of a reflector (I am speaking of light, but lower frequencies doesn't alter the situation). That is to say, there is no infinitesimally thin boundary through which energy does not pass - even for a perfect reflector.

In antennas, we call this zone the reactive field.

Hence, the reflection seeing the mismatch of the tuner/tuned output, finds its way beyond the connector, back into the internals, passing through transform circuitry.

To Richard C:

Richard, I must totally disagree that the same degree of mismatch occurs at the tx output as at the dissipative load, the antenna. As I have said many times, with the non-dissipative output source impedance of the RF amp (tubes) the reflection at the junction of the line input and the pi-network output is total. In other words, all of the reflected power incident on the output of the pi-network is TOTALLY re-reflected. Can't be anything less!

To Richard F. And I disagree that the load mismatched at 2:1 absorbs 88.8889% of the forward power. It is 90% !!! We are discussing steady-state values, in which arrival of the first forward wave is irrelevant. If you are so confident that the number is 88.8889%, please derive the conditions that yield that number.

I never thought I'd be having this discussion.

Walt

Hi Walt,

There's an active load behind that 2:1 mismatch seen by the reflected power returning from the load. That is my part of the discussion.

However, if you are going to neglect that interpretation, then there must be some explanation for TOTAL reflection. Fortunately there is, it is called an open, or a short.

Now, we come to a philosophical quandry of the "Conjugate Match." If we tune to a load, and we guarantee that the tune is the conjugate of the load, then at any point along the transmission line in between there exists looking at either end a conjugate of the opposite end.

In other words, putting a network analyzer into the line looking at the load it sees R +jX, and looking back at the source it sees R -jX. This is conjugation. Moving the analyzer along the length of the line will transform R and X, but they will always track to a solution of the conjugate.

You've been arguing this for years.

And, as the load is neither a short, nor an open (which is a special solution of conjugation); then it stands to reason it is something other which necessarily demands a solution in the form of:

R �jX

from the source, where R has some non-zero, and non-infinite value. For trivial antennas, that value of R falls somewhere between the 10s of Ohms and the 100s of Ohms. For trivial, retail transmitters available to Hams, similar values of R abound but most often fall closest to 50 Ohms, or they would have a hard time getting optimal power into the 50 Ohm pipe. Vendors are not going to shoot themselves in the foot before that race.

A TOTAL reflection is available courtesy of the "active" part of this special load. The "active" load (the transmitter sinking the reflected power from the dissipative load) can offer one of two mechanisms to provide the necessary short or open. When the source wave coming out meets the returning wave coming in, and they are phase coherent at 0 degree difference, then there is no potential difference through the connector - no current flow. No current flow = open circuit. Open circuit satisfies TOTAL reflection mechanics (but violates conjugation). If they are phase coherent, but 180 degrees different, then there is maximum current = short circuit. Short circuit satisfies TOTAL reflection mechanics (but violates conjugation).

However, in either of these scenarios, both powers (actually energies) must be equal. Obviously that isn't the case with a nominal 100W source looking at a 10W reflection.

Hence the analysis draws out slightly more along the lines I've already posted and won't repeat here.

However, for the sake of argument, the condition of tune (conjugation) and the state of coherency (a slippery slope, but here we are), combine through a ringing in the line to create a virtual TOTAL reflection at the connector of the Tuner/tuned amplifier. So, Walt, I am not denying your case, but in the earlier posting I do preserve conjugation in the explanation.

No transmitter, even with the best of tuning attempting to match will forgive a short or open as load however. And, yes Richard, I have experienced such conditions with 10s of W to 100s of kW and not all of them accidental.

Another issue of moving sensors along the transmission line between high mismatches is that there will be considerable error in the determination of power - I presume this is where Jim's bookkeeping explanation will lead, but that is still hanging on the line (no pun there). I have experience the difficulty of those conditions too when making precision power measurements.

=C3 =3D R(load) - R(source) / R(load) + R(source)

SWR =3D (1 + |=C3|) / (1 - |=C3|)

Power Accepted by the Load =3D Incident Power * (1 - =C3^2)

For a 50 ohm source connected to a 100 ohm load:

=C3 =3D (100 - 50) / (100 + 50) =3D 50 / 150 =3D 0.333333...

SWR =3D (1 + 0.333333) / (1 - 0.333333) =3D 1.333333 / 0.666666 =3D 2:1

Load Power =3D Incident Power * (1 - 0.333333^2) =3D Incident Power * 0.888889 (or 88.8889%)

The answers are the same for a 50 ohm source with a 25 ohm load.

Or expressed another way a 2:1 vswr equates to a return loss of 9.542dB
and so a mismatch loss of -0.512dB which equates to 0.888 or 88.8% .

It may be possible to get the performance of the Lazy H antenna up by matching it at the antenna with a 1/4 matching stub, but clearly running 100 feet of 450 ohm ladder line from the center of the Lazy H back to an antenna tuner does not work very well on 10 meters.   I took the Lazy H down yesterday and put up the previously mentioned extended double zepp using the same support ropes, and the extended double zepp out performed the dipole on every A/B comparison in it's preferred direction.

May I suggest that we simplify the example by removing the tuner from
the discussion?

100w--+----1/4WL 100 ohm feedline----200 ohm load

Same conditions as before. The voltage reflection coefficient at the
load is 0.3333. The power reflection coefficient at the load is
0.1111. A 50 ohm Z0-match exists at point '+' without a tuner. No
reflected energy reaches the source.

Hello Walt,

The source (that is the PA in this case) produces an EMF (as mentioned before) of 212.1Vrms, Source impedance is 100 Ohms (so forget the "conjugated match" thing for this case).

When terminated according to the numbers above the socket ("100W into 50 Ohms"), this results in 100W (Vout =3D 212.1*50/(50+100) =3D 70.7V, just a voltage divider consisting of 100 Ohms and 50 Ohms).

70.7V into 50 Ohms makes 100W.

Now we remove the 50 Ohms load and create a mismatch (referenced to 50 Ohms), by connecting a 100 Ohms load (VSWR =3D 100/50 =3D 2)

Now the output voltage will be:

Vout =3D 212.1*100/(100 +100) =3D 106V

106V into 100 Ohms makes 112W (forgive me the one Watt difference).

This all without any transmission line theory.

Now the forward and reflected power balance (this is exactly the same as in my previous posting, except for using 112W instead of 111W):

100 Ohms equals |rc| =3D 0.3333 (50 Ohms reference).

Hence "reflected power" =3D 0.333^2*"incident power" =3D 0.111*"incident power".

"net delivered power" =3D "incident power" =96 "reflected power" =3D 112W.

"net delivered power" =3D (1-0.11111)*"incident power" =3D 112W.

"incident power"=3D 126W, "reflected power" =3D 14 W

As far as I can see, there is nothing new with respect to the previous calculation, except for the truncation/rounding.

Similar reasoning can be applied to my class-E PA. It is designed for 500W into 4.5 Ohm, but the output impedance is below 1 Ohms. If you try to achieve conjugate match, you fry the active devices. Same is valid for most audio amplifiers, they may mention: "80W into 8 Ohm", but that does not mean that Zout =3D 8 Ohms.

Awaiting your comment,

Wim

To Walt: (Steady state) Load conditions can be specified in many forms
(complex impedance, complex reflection coefficient, VSWR with phase,
etc), but depending on the actual integral of the Vp*Ip product, the
plate's dissipation may decrease or increase (due to a load change).

So changing the load (without retuning as you mentioned below) may put
your tubes at risk. Your qualification below seems to contradict your
statement above.

To Richard C.: It seems to me that you're overlooking the fact that the source resistance appearing at the output terminals of the pi-network is non-dissipative, and thus cannot absorb the energy in the reflected wave incident on it. The resistance is E/I and therefore non-dissipative, has a real value and is thus a part of the conjugation. The result is total re-reflection, no transfer of energy into the amp. I thought I'd made this very clear over the years.

To Richard F. My humble apology for my moronic error. My bad!!! I can't believe I was so stupid as to not know where the 0.888889 came from. Thanks for spelling it out for me. I got totally sidetracked with the 100/111,11 =3D 0.90, and didn't see any farther.

Wim: I'm working on your response--it's finally beginning to make sense--gimme a few more minutes.

Walt

Not replying to anyone in particular - Because I can post graphics directly to QRZ, I have started a thread on the antenna forum at:

http://forums.qrz.com/showthread.php?296735-Pi-Net-Tuner-Brainteaser

It is my contention that reflections are eliminated by a Z0-match which, in a tuner system, occurs at the *input* to the tuner.

Gotcha.  Yeah, a dipole would be simple enough.

Hi Michael,

And for the double zepp, that merely confirms what is reasonable. By virtue of its length and phase relationships, its investment above and beyond the dipole tracks with gain.

However, matching stubs are not going to discover the missing gain for the Lazy H.

As for 100 feet of 450 Ohm ladder line - nothing wrong with that, even at 10 meters.

I've never tried one, so can't say from experience.
But that you have to use extreme tuner settings to match
the system tells me you may be seeing a good amount of loss.
And then you have the issues Richard mentioned on top of that.
The coax fed dipole is very efficient. Very little system loss
involved. So even if it had less directional gain, it's possible
that gain could be offset by matching losses. Or even driven
negative if the loss was extreme. :(
Compare the two on a dead frequency just listening to noise.
If the H seems real quiet compared to the dipole, I would
suspect excess tuner loss. If they are about the same, may be
other issues.

The only phased dipoles I ever ran were parallel horizontal
dipoles. I would steer the pattern by changing the phasing.
Usually by adding lengths of feed line. It worked pretty well.
That was on 40m.. But as mentioned, there is only so much
blood that can be squeezed from two elements, even if configured
in an optimum manner, say as with a yagi or whatever. :/

I rebuilt the center fed Lazy H twice with different pieces of 450 ladder line, and I installed it in two different locations. I used two different antenna tuners. I built it exactly as specified in the ARRL antenna handbook. Both times the antenna exhibited a high SWR and poor performance compared to a mono band dipole for the same frequency and at about the same height. I suspect the underling problem may be too many arm chair antenna experts plugging their designs in to computer antenna modeling software, and not enough people actually going out in the backyard and building the antenna and comparing it's performance to a real world dipole for the same frequency. There are many web pages touting the supposed gain of the Lazy H with EZNEC plots posted as supporting evidence, but real world performance has shown that it is consistently out performed by a plain old dipole.

I was able to make contacts with the Lazy H, and I did get some good reports with it. However, when I switched to the plain old wire dipole the dipole was consistently the stronger performer. I have not tried the end fed Lazy H design with a 180 degree twist and the 1/4 wave matching stub yet.

Hi Michael,

All very true, but be careful of the conclusions you thinks this leads you to. For instance:

>There are
>many web pages touting the supposed gain of the Lazy H with EZNEC
>plots posted as supporting evidence, but real world performance has
>shown that it is consistently out performed by a plain old dipole.

The Lazy H, in professional installations known as Sterba Curtains, are THE antenna of the big gun Shortwave Broadcasters. Engineers, stations, and their backers looking at field data do not erect costly antennas without good judgment. In the past, we have had contributors here who have designed for these big guns.

Now, as to what you see as "evidence" on the Web in the form of EZNEC software reports (something I've been using for nigh-on 20 years) has to be looked at in the details, and the details that are significant:
1. The presence of ground
2. The quality of ground
3. The antenna elevation above ground
4. The presence of conductor loss
5. Transmission line specification
6. Transmission line drive
7. The load Z
8. The system gain (or loss)
at a minimum. That is a lot of detail to hold in the mind while trying to compare two antennas, much less 3, 4, or 5.

One of the glaring mistakes between the outcome to this and "reality" (and this undoubtedly conforms to your experience) is that the placement of the source (transmitter) in software is vastly different than the placement of the transmitter (source) in physical reality.

For instance, the twist in the line between elements is to enforce a necessary phase relationship so that you can fee it at the bottom. Otherwise you can go with a non-twist if you feed it in the middle. The design varies in particulars there. So what? You can feed either a twisted connection, or a non-twisted section in the middle; BUT for the second version, the line back to the transmitter MUST BE dressed AWAY from the middle of the interconnecting line. Proximity will confound everything. Proximity for this second choice is almost guaranteed in a casual installation where an EZNEC "schematic" of the system offers only a blob called "source" in a spot of convenience that does not exist in reality.

So, the long and short of it is:
 Do not feed in the middle of the interconnecting line.
 Observe proper phasing requirements.

You can perform your own EZNEC analysis using the free version. The benefit of this is you can control all the variables, adjust items 1 through 6 in the list above, and you can replicate your experience. Doing this will also reveal what you need to do to optimize your antenna.

The W8JI web page goes to considerable length to bash the end fed Lazy H with the twist, but since the real world performance of the center fed Lazy H is less than stellar I'll have to give it a try.

There is one thing the center fed Lazy H did better than the dipole and the extended double zepp. When I applied RF to the center fed Lazy H four of my outside motion sensor flood lights would come on. I guess if I wanted to go outside at night I could just switch to the Lazy H, key the mic, and save myself a trip to the light switch. ha ha

W8JI bashing the end fed Lazy H with the twist

You got it.

Feed them in phase.

Maybe.. depends on the antenna.

But consider that they might actually have a 75 ohm impedance, which
will be close to what you need.
